D. R. MacLeod (General Electric Company, Erie, Pa.): We agree with Brecht and Kerr that it would be very desirable to build a more standardized electric locomotive than we have in the past. We do not agree with the method of standardization that they have suggested. It is just as desirable to standardize locomotive manufacture as it is to standardize the component parts. The type of locomotive described in the paper would have different unit lengths for the different ratings. This is a serious disadvantage from the standpoint of the locomotive builder. For example, a locomotive 117 feet long would require facilities that are not available in a shop equipped to build large quantities of locomotives that are half the length.

The details of design are not described and detailed analysis and layouts would have to be made to evaluate the proposed design. The general description of the mechanical arrangement appears to be quite feasible. Our experience in building locomotives with span bolsters has revealed many disadvantages of this type of construction that are not readily apparent. It is the writer's opinion that the 5,625 and 7,500 horsepower locomotives would be a better over-all job if built in two cabs of the smaller units.

The statement is made that one traction motor can be used with 45,000 pounds per axle with the different gearing required for switching, freight or passenger service. This is very interesting and deserves further explanation. Alternating current series motors of the type in general use today are applied on the basis of a certain volts per bar when starting at 25 per cent adhesion. With the same weight on the drivers in all cases, the volts per bar when starting at 25 per cent adhesion will be approximately in proportion to the maximum speeds for which the locomotives are geared.

The authors state that the optimum adhesive weight ratio for an electric locomotive appears to be about 100 pounds for each rail horsepower. We do not believe that there is any single weight ratio that will fit all applications. During the last twelve months the General Electric Company has completed the largest single-cab electric locomotives and four electric locomotives with the greatest adhesive weight that have been built to date. These locomotives had an adhesive weight of approximately 150 pounds per rail horsepower. Higher horsepower in relation to weight on drivers was not required. On the other hand, there are applications of high-speed passenger locomotives where an adhesive weight of less than 100 pounds can be used to advantage. The optimum weight ratio for a given application is the ratio of the adhesive weight that is required to negotiate the heaviest grade divided by the maximum horsepower that can be used to advantage anywhere on the profile. A Diesel-electric locomotive designed for freight service has a high continuous tractive effort rating which enables it to haul heavy trains over heavy grades. A 4,500 horsepower Alco-GE Diesel-electric locomotive has a higher continuous tractive effort than the 7,500 horsepower (at the rail) locomotive illustrated by Figure 3 of the paper. It can haul the same tons as the 7,500 horsepower locomotive over a ruling grade but must do it at a slower speed. The higher the speed that is to be maintained over the entire profile the higher is the horsepower required and the lower is the weight ratio in pounds per horsepower that is desirable.

Any standardization that is adopted for electric locomotives should be capable of sufficient variations so that their inherent flexibility is not handicapped.

C. K. Steins (The Pennsylvania Railroad, Philadelphia, Pa.): Brecht and Kerr have presented a very interesting conception of the electric locomotive of the future. They propose to standardize locomotives below the cab underframe and perhaps it is planned to carry this standardization into the cab itself, although their necessarily brief paper does not bring this out clearly.

It should be possible in this locomotive to house the cab apparatus for, say, two trucks in the cab length over these two trucks which would mean the transformer, switching apparatus, blowers, and so forth, for these two units would be a package. This would mean building the locomotive in multiples of two trucks and the 2,813 horsepower locomotive shown in Table I in the paper would be dropped out, but if steam and electric locomotive builders are going to get into a competitive position with Diesels they will be wise to take a page from the Diesel book and stop making custom-built engines. Everyone knows the resistance of the Diesel builders to changes but it is obvious that locomotives simply cannot be built cheaply in any other way. It is a well-known fact that steam locomotive costs have suffered because one railroad will usually not accept a locomotive designed for another road; in fact, repeat orders on the same railroad call for engineering changes that affect costs.

There is an advantage in manufacturing the cab apparatus in package units aside from lower production costs. I refer to the ability to bring the train in with fractional power in case of a failure. For example, if a traction motor is lost on the 7,500 horsepower unit shown, it is presumed that that truck would be cut out and the train brought in with 7/8 of the engine. If a transformer is lost, assuming the cab apparatus is made up of package groups connected in parallel, each group serving two trucks, the locomotive could still haul its train in with three-fourths of its rated power. Everyone knows that this flexibility has been a great thing for the Diesels; many a train has been brought in on time with a Diesel engine inoperative and the Diesel gets credited with a perfect performance, which, of course, is right and proper from an operating standpoint.

We would anticipate some engineering difficulties in building the 2,813 and 3,750 horsepower locomotives in the table in which no equalization is indicated between trucks. The authors state that by using soft springs the weight transfer can be held to less than 5 per cent. The writer has had some experience with weight transfer on steam locomotives; there are intangibles in this problem that, to say the least, are difficult to resolve. Even the designs with equalizers would have to be carefully studied as there is not much background for this

construction and heavy equalizers appear to have a time lag in their response and this may be enough to start a slip. Soft springs undoubtedly are a "must" but there are worn wheels and new wheels to consider and it seems to the writer that the best protection is to undermotor the axles to, say, a maximum of 400 horsepower per axle rather than the 469 horsepower suggested.

H. F. Brown (New York, New Haven and Hartford Railroad, New Haven, Conn.): Brecht and Kerr have made a real contribution to the technical bibliography of electric locomotive design in their paper.

It is of especial interest to learn that the a-c motor design has progressed to the extent that it can be applied to a standard truck design almost interchangeably with the d-c motor design, as to weight, dimensions, and performance. The relative costs given of the various types of locomotives (steam, Diesel-electric, and electric) are of exceptional interest, and worthy of a little discussion to see where each fits into the modern transportation picture.

Applying these cost ratios to new locomotives, all having approximately the same rail horsepower, a set of comparative costs per locomotive per year can be set up as in the Table I of this discussion. It will be assumed that power costs for all three types are about equal. This is always debatable, but if there are known differentials favoring one type of motive power over another, these can be applied later. It will also be assumed that engine-house expenses are about the same for Diesel-electric and straight electric, and that these are lower than for steam for the same service. It will also be assumed that operating labor expenses are the same for all three types. On the basis of these assumptions, Table I of this discussion indicates that it may be cheaper to own and maintain a steam locomotive if mileages of more than 100,000 per year per locomotive cannot be attained. If greater annual mileage and more intensive use can be made with certain locomotives, they can be Diesel-electric, with marked economy over steam; but since certain locomotive services have low annual mileage, it is not always economic to completely Dieselize unless it can be shown that the average mileage of all locomotives is 100,000 per year or more, or unless there are other compelling economic factors.

Turning now to the comparison between Diesel-electric and straight electric, it will be seen that even with very low annual mileages per locomotive, it is always cheaper to use the electric locomotive where electrification of the line already exists. In other words, Diesels cannot be operated economically into electrified territory. Similarly, an existing electrification might be profitably extended, if more annual miles per electric locomotive could be realized by so doing, as compared with Diesel locomotives unable to make a much larger annual mileage per unit, in the same service.

Where a new electrification project is being considered, the number of locomotives required, multiplied by the annual saving per locomotive of electric over Diesel as given in the following tabulation, for the expected locomotive miles per year, is a fair index of the amount of capital which could be invested in electrification over and above the locomotive costs.

Table I

	Diesel	Electric	Steam
Cost Ratio	100	68	50
Rail Horsepower	3,750	3,750	3,750
Cost per hp	$110	75	55
Cost per Locomotive	$413,000	$281,000	$206,000
Fixed Charges at 10% per year	41,300	28,100	20,600
Assumed Average Maintenance cost per locomotive mile over life	30¢	20¢	50¢
Fixed Charges per locomotive mile			
@ 50,000 mi./yr.	82.6¢	56.2¢	41.2¢
@ 100,000 " "	41.3¢	28.1¢	20.6¢
@ 150,000 " "	27.5¢	18.7¢	13.7¢
@ 200,000 " "	20.7¢	14.1¢	10.3¢
@ 250,000 " "	16.5¢	11.3¢	8.3¢
@ 300,000 " "	13.8¢	9.4¢	6.9¢
Cost of owning and maintaining each locomotive per year			
Fixed Charges plus (maintenance per mile × mile per year)			
@ 50,000 mi./yr.	$56,200	$38,000	$45,600
@ 100,000 " "	71,300	48,100	70,600
@ 150,000 " "	86,500	58,100	95,500
@ 200,000 " "	101,400	68,200	120,600
@ 250,000 " "	116,000	79,000	145,500
@ 300,000 " "	130,000	81,000	165,600

Miles Per Locomotive Per Year	Annual Saving in Fixed Charges and Maintenance Per Electric Locomotive Over Diesel
50,000	$18,200
100,000	23,200
150,000	28,200
200,000	33,200
250,000	38,200
300,000	43,200

For example, if a certain railroad division required 50 locomotives for its operation, and they could average 100,000 miles per locomotive per year, the saving in electric operation over Diesel would be 50×$23,200 or $1,160,000. If the line could be electrified for, say, ten times this amount, or for $11,600,000, it might be a very good investment. This points to a much shorter line, with much heavier traffic, or with a cheaper electrification, than the one discussed by Kimball and Holm.[1]

Dense traffic always favors electrification; light or medium traffic is harder to prove in, except in the case of an extension to an existing electrification, if and when more locomotive miles per unit can be realized. In such a case the savings, capitalized, of electric locomotives over Diesels, as previously outlined added to the capital costs of Diesel locomotives required, would justify even greater capital expenditures for such an electrification.

One of the principal reasons why Diesels are being purchased in preference to electrifying the railroad is that they can always be bought a few at a time with equipment trust certificates, and these first few units can be worked very intensively; whereas electrification must be done over a definite section of the line all at once, which requires a considerable amount of new capital, in addition to that required for the electric locomotives, all of which must also be purchased at the same time.

Brecht and Kerr have stimulated a new interest in electric motive power by their paper. If the maintenance costs mentioned of 1/3 to 1/2 that of maintaining Diesels or reciprocating steam engines of the same horsepower can be realized, the savings mentioned in this discussion can be much larger, as the maintenance costs mentioned herein for electric are assumed to be 2/3 that for Diesels.

W. A. Brecht and Charles Kerr, Jr.: C. K. Steins, in his discussion of this paper, points out the necessity for standardization to reduce first cost, and also, the desirability for building electric locomotives so that a road failure of any particular part will not prohibit the locomotive completing its assigned run. The authors thoroughly agree with Steins' remarks.

In connection with Steins' comments about weight transfer, the control on these locomotives has been designed to minimize wheel slippage and the authors believe that this factor can be minimized to satisfactory limits.

H. F. Brown has submitted some very pertinent comments regarding the economies of electric operation. A discussion of over-all economies was beyond the scope of our paper and we feel that he has made a very excellent contribution by including such discussion.

D. R. MacLeod has raised several objections to the authors' proposed standardized design of electric locomotives. Many of his objections we do not agree with, but it must be realized that any standardization program always requires certain sacrifices in design. It is our contention that electrification needs, above all else, a reduced first cost, and this can only be achieved by standardizing its component parts. The advantages of so doing greatly outweigh the disadvantages.

Synopsis: Duquesne Light Company placed in service on October 26, 1947, the largest kilovolt-ampere and highest voltage-series capacitor in the world, to improve voltage regulation and alleviate voltage flicker at a large steel mill and on the line serving it. The capacitor has a nominal rating of 10,000-kva and was installed on a 66-kv line. It was built by the Westinghouse Electric Corporation. This paper presents the calculated results of system studies made prior to the authorization of the series capacitor and the reasons for selecting the series capacitor. In addition, the results of staged tests showing the starting of a large induction motor and the energizing of the power transformers at the load with the capacitor in service are included. The improvement in utilization voltage is also shown.

THE 66-kv 14-mile 4/0 line, to which the capacitor is connected, is a direct open-wire circuit from the Phillips power plant to the 66-kv bus of the Crucible Steel Company. The steel company receives its power from the line through four step-down transformer banks operating in parallel. The banks have a total name-plate rating of 44,200 kva and are connected 66,000/12,000 volts; the windings are connected delta on the high side and wye on the low side, with the low side neutral solidly grounded.

Figure 1 shows the 66-kv transmission lines, substations and generating stations of the Duquesne Light System, with the Phillips–Crucible line and the series capacitor substation (Kennedy Substation) at the left center.

The Phillips–Crucible line was recently tapped at a point near Crucible to provide standby service for six 22-kv customers and a 4-kv substation in the Midland district through a 66/22 kv bank shown on Figure 1 at the left center. The Midland district load was served normally by one long 22-kv line with severe exposure. This line is not shown on Figure 1. With the series capacitor in the Phillips–Crucible line, it is possible to supply the Midland district normally from the 66-kv line, which was not possible because of wide voltage regulation and severe voltage flicker prior to the installation of the series capacitor.

Customer's Load

The present load at Crucible consists mainly of four 10,000-kva electric arc furnaces, one 4,000-horsepower induction motor (motor-generator set), one 800-horsepower synchronous motor, two 3,000-horsepower synchronous motors, and two 1,000-kva synchronous motor-generator sets. Additional load is expected in the future.

The electric arc furnaces cause rapidly fluctuating loads to be drawn from the Duquesne Light System. When the furnaces melt down, the load frequently exceeds the normal 15-minute billing load and at a lower power factor. The 15-minute billing load in general determines the effective load on the supply line and transformers. The instantaneous load, which may last only a few minutes, determines the voltage regulation at the customer's 11-kv bus and at other points along the supply line.

The Crucible 15-minute billing load is 28,000 kw at 87.5 per cent power factor or 32,000 kva. The instantaneous load is 28,600 kw at 78.3 per cent power factor or 36,500 kva.

Voltage and Flicker Conditions at Crucible Prior to Series Capacitor Installation

The Crucible instantaneous peak load of 28,600 kw at 78.3 per cent power factor caused Crucible voltage to drop from the no load value of 11,900-volts to 9,800-volts, or 119-to-98-volts in low voltage or 110-volt terms. Hereafter, voltages will be expressed in 110-volt terms for convenience, and are equivalent to 11,000 volts divided by 100 or 66,000-volts divided by 600. Occasionally, the Crucible voltage ranged from 121 volts at no load to 98 volts at full load. Figure 2 (curve *A*) shows 11-kv voltage at Crucible before the series capacitor was installed.

In addition to the excessive regulation, the furnace loads fluctuate so rapidly that they cause severe instantaneous voltage drops or voltage fluctuations on the 11-kv bus and 66-kv bus at Crucible, and poor voltage regulation and less severe voltage fluctuations at other points along the 66-kv line. These voltage fluctuations are generally termed light flicker and were calculated to be nine volts on the customer's 11-kv bus in 110-volt terms. These fluctuations are of varying frequency and may reach a rate of one per second.

The wide regulation range is not too serious as far as furnace operation is concerned, but it has caused some trouble in motor operation. The condition has existed for some time, but it was not possible to remedy it during the war. The

Paper 48-55, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 12, 1947; made available for printing December 9, 1947.

B. M. Jones is planning engineer, J. M. Arthur is development engineer, and C. M. Stearns is senior development engineer with the Duquesne Light Company, Pittsburgh, Pa.; A. A. Johnson is central station engineer, with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

initial requirements for the series capacitor were established on December 14, 1945, and actual authorization by letter was given on January 4, 1946.

Voltage and Flicker Conditions at Crucible With the Series Capacitor In Service

After studying several types of corrective equipment, the 10,000-kva series capacitor was selected as the most economical and satisfactory device for improving voltage and reducing lamp flicker. A more detailed discussion on the types of equipment considered will be reviewed later in this paper.

With the series capacitor in service, it has been calculated that the 11-kv bus voltage at Crucible will range (total) between 121 volts and 110.5 volts, and the lamp flicker voltage will be 4.5 volts. Figure 2 (Curve *B*) shows the 11-kv voltage at Crucible after the capacitor was installed. Figure 3 shows a graph of the calculated voltage at various points on the line between Phillips Power Station and the 11-kv Crucible bus before and after the series capacitor was placed in service.

During the past few years, Crucible has experienced some unsatisfactory motor operation (running and starting) during heavy furnace load periods, because of low voltages and voltage unbalance caused by furnace operation. With the series capacitor installation, these troubles should be entirely eliminated.

Voltage at Midland

Reduced voltage regulation and reduced lamp flicker along the Phillips–Crucible line on the load side of the capacitor enables the Duquesne Light Company to use the tap from the Phillips–Crucible line through a step-down bank for normal service to the Midland district. The 10,000-kva step-down transformer bank is connected 69,300/24,250. The present single long 22-kv line can now be retained as a standby.

Figures 4*A* and 4*B* show a chart of the voltage on the 22-kv bus at Midland substation when supplied from the 66-kv line before and after the capacitor was installed, respectively.

Methods Considered For Correcting Voltage

For improving the voltage regulation and flicker conditions at Crucible, the following types of corrective equipment were considered.

1. Voltage regulator (step-type) for motor load alone.
2. Synchronous condenser.
3. Switched shunt capacitors.
4. Second 66-kv line.
5. Series capacitor.

A brief discussion of the types of corrective equipment considered follows.

Voltage Regulator

Voltage regulators require a change of voltage to actuate them, and then frequently by the time voltage is corrected the excess current demand has ceased and over-compensation in voltage results. In addition, a time delay device must be used to reduce the number of operations. Therefore, a voltage regulator is not suited for regulating rapidly changing voltage or correcting flicker.

A small laboratory regulator was designed and constructed by the light company to indicate the number of times it would actually need to operate with certain time delay and with various amounts of voltage correction. Operation of this regulator indicated that, for instance, with 10 seconds time interval between tap changes, the tap changes per year would vary between 100,000 and 400,000 for ±4 volts and ±2 volts, respectively. It was believed that operations of this magnitude would cause excessive maintenance.

The cost of reconnecting the three circuits supplying the motor load to a regulator would be expensive. It was also agreed that all load, including furnace load, should be regulated and for the reasons cited, the regulator idea was dropped.

Synchronous Condensers

Synchronous condensers, connected at the load, unlike voltage regulators, would be effective in reducing lamp flicker as well as voltage regulation. With instantaneous changes in load, the inherent characteristics of synchronous condensers help to limit voltage change by supplying part of the reactive kilovolt-amperes required, thereby reducing light flicker. This is accomplished because of the instantaneous change in output of a condenser which takes place with sudden changes in terminal voltage. A synchronous condenser to provide the same improvement in voltage regulation as the series capacitor would need to be approximately 50 per cent greater in kilovolt-ampere capacity. The improvement in light flicker with this size condenser is not as great as that with the series capacitor. The installed cost, losses, and operating and maintenance costs for the synchronous condenser would be considerably higher

Figure 2. Crucible 11-kv voltage charts with heavy furnace load

(A) Before series capacitor installation
(B) After series capacitor installation

Figure 3. Voltage diagram showing regulation on Phillips–Crucible 66-kv line and on Crucible 11-kv bus before and after series capacitor installation

than for the series capacitor. Unless two condensers were installed, the problem of breakdown would be present. A buffer reactor could not be used with the condenser, since the problem was to improve voltage on the customer's bus as well as on the supply line.

Switched Shunt Capacitors

Consideration was given to connecting a group of shunt capacitors to each of the four furnace circuits, to be switched with the furnace, and to connecting another unswitched group to the 11-kv bus. Such an arrangement did not prove feasible, since furnace refining loads are low and at a good power factor and capacitors would be in service when not needed, thus possibly increasing the voltage regulation band. Furthermore, shunt capacitors would aggravate light flicker since the ampere load taken by the capacitors varies directly with the voltage. Switching of shunt capacitors to follow rapidly changing loads in any manner other than described before would be impractical.

Second 66-kv Line

A second 66-kv line from Phillips to Crucible was also considered as a method of alleviating the voltage and flicker problem. With two lines to Crucible, the minimum voltage on the 11-kv mill bus would be 104 volts compared with 110 volts delivered by the series capacitor. The second line would be expensive.

Series Capacitor

A series capacitor was selected since it is fundamentally suited to reducing flicker and improving voltage, doing both efficiently and at relatively low cost. It is inherently automatic in operation, since it introduces a voltage which leads the current 90 degrees and is directly proportional to the magnitude of current. The capacitive reactance voltage instantaneously compensates for a like amount of line inductive reactance voltage for all values of the current, alleviating rapid voltage fluctuations and reducing voltage drop.

Since a series capacitor reduces the impedance of a line, it increases, in effect, the capacity of the line because of increased utilization voltage. Stated another way, increased kilovolt-ampere loads can be carried with the same voltage drop, or the same kilovolt-amperes can be carried with less current. With the 10,000-kva series capacitor in the Phillips–Crucible line, current values are reduced 10 per cent for the same delivered kilovolt-ampere load.

If the Crucible load increases, and a second line from Phillips to Crucible is required to carry the line amperes, the series capacitor will also be needed and can be used advantageously. This can be done by carrying the second line through the capacitor and increasing the thermal rating and reducing the ohmic value of the capacitor.

Size and Location of Series Capacitor

Size of Capacitor

The proper size of a series capacitor depends in general on:

1. The maximum ampere load of the circuit, giving consideration to possible growth.
2. Amount of voltage improvement desired.
3. The ohms reactance of the line and transformer banks involved.

Although the present ampere load at Crucible is less than the 500-ampere rating of the 66-kv line, it is expected that the load will grow. Therefore, the rating of the capacitor was selected as 500 amperes.

Calculations indicated that the inductive reactance from Phillips Power Station to the Crucible 11-kv bus must be reduced approximately 14 ohms in order to raise the minimum voltage to 110 volts with loads of about 30,000 kw at around 80 per cent power factor. A capacitive reactance of 14 ohms would compensate for the reactance of the Phillips–Crucible line of 11.49 ohms plus most of the system reactance at the Phillips bus of 3.59 ohms. A 14-ohm series capacitor on a circuit carrying 500 amperes has a voltage drop across the capacitor of 7,000 volts per line. Since 7,000-volt capacitors do not exist, or at least are not standard capacitors, 3 2,400-volt 15-kva capacitors in series were selected.

Capacitors of 2,400 volts allow the use of standard protective devices, such as protective gaps and by-pass switches. The 2,400-volt capacitors will also be useful elsewhere on the Duquesne Light System should the capacitor installation ever be abandoned.

After the 2,400-volt 15-kva unit capacitor was decided upon, the total number of units was determined by using the rated ampere values of each unit, namely 6.25 amperes. Since the series capacitor must have a 500-ampere rating, 80 units were provided in parallel. The nominal impedance of each unit is 384 ohms, and the total impedance of 80 such units in parallel would be 4.8 ohms or 14.4 ohms for three groups in series.

Standard 15-kva capacitor units have a guaranteed tolerance in rating of minus 0 per cent and up to plus 13 per cent. This means that the impedance of each

Figure 4. Midland 22-kv voltage charts with heavy furnace load at Crucible

(A) Before series capacitor installation
(B) After series capacitor installation

15-kva unit may vary between 384 ohms and 340 ohms. Assuming an average distribution of 362 ohms, the total capacitor impedance is approximately 13.5 ohms.

Calculations indicate that with a 500-ampere 13.5-ohm series capacitor, the present instantaneous load of 28,600 kw at a power factor of 78.3 per cent would result in a maximum regulation range of 121 to 110.5 volts. This was considered satisfactory.

Location of Capacitor

Where load is not distributed along the line, a series capacitor can be placed in general at any location on the supply side of the load. The capacitor should be located so that the maximum fault current on the load side of the capacitor does not exceed the momentary rating of the protective devices. Furthermore, it should be so located that the terminal voltage on the load side does not exceed the voltage of lightning arresters normally used by the power company. Accessibility is an important point in locating the capacitor.

The following table shows the impedances of the Phillips–Crucible line ahead of the capacitor and from the capacitor to the Crucible 11-kv bus.

0+j 3.59	Phillips bus
2.59+j 7.67	Phillips to Kennedy
0.73+j 2.05	Kennedy to Midland tap
0.62+j 1.77	Midland tap to Crucible bank
0.69+j 8.60	Crucible bank
4.63+j 23.68	Total
0−j 13.50	Kennedy Substation (Series Capacitor)
4.63+j10.18	Net impedance

Diagram of Series Capacitor

Figure 5 shows the simplified connections of the series capacitor shunted with a resistor. The resistor is necessary to solve the series capacitor application problems. A detailed description of the capacitor and its protective equipment is given in companion papers.[1,2]

Series Capacitor Application Problems

Before a definite decision was made to install the series capacitor, an investigation was made of series capacitor application problems and troubles experienced by other power companies. These troubles were found to be:

1. Distorted and excessively large transformer exciting current upon energizing an unloaded bank. This condition is known as "ferroresonance."

Figure 5. Series capacitor diagram showing three groups of capacitors with their protective devices, four 400-ohm shunting resistors, 66-kv line airbreak switches, and grounding switch

2. Hunting of lightly loaded synchronous motors.

3. Self-excitation of induction motors and synchronous motors which start as induction motors.

Ferroresonance

When voltage is first applied to an unloaded transformer, a high inrush of current may result if this voltage is applied near the zero point of the voltage wave. This is because flux in the transformer tends to double in value during the first half cycle, and with high values of flux the effective inductance of a transformer becomes very low. Because of low inductance, excessive currents (magnetizing currents) may flow for several cycles after which the transformer draws its usual low value of exciting current. However, it has been found that occasionally when a transformer is supplied through a series capacitor without a shunting resistor, the initial excessive currents which may normally prevail for a few cycles may continue to persist in the steady state. This current may be greater than rated current of the bank, and is apparently of a low frequency, resulting in badly distorted current and voltage waves. These abnormal steady-state currents flow when the voltage is applied near the zero point of the wave just as the high transient occurs for this condition in the ordinary case without the series capacitor. A complete qualitative explanation of this phenomenon is covered in a paper published in 1937.[3]

Because of the nonlinear characteristics of a transformer, mathematical analysis of the problem is very difficult, and no satisfactory analytical solution has as yet been found. However, it has been found from experience that ferroresonance can be eliminated by shunting the capacitor with a resistor or by having a certain amount of load on the load side of the series capacitor.

Should ferroresonance occur on the Phillips–Crucible line with the series capacitor, the resistor shunting the capacitor to prevent self-excitation of motors, covered later in this paper, will also prevent ferroresonance.

Hunting of Synchronous Motors

A synchronous motor when lightly loaded is sensitive to system disturbances, such as switching, changes in load, pulsating load, and changes in excitation. The main factor in determining whether a synchronous motor will hunt with the installation of a series capacitor, is whether the ratio of system resistance to system reactance up to the motor's terminals is large or small. After installing a capacitor, if the ratio of line resistance to equivalent reactance is considerably higher than unity, then there is a good possibility of synchronous motors hunting. On the other hand, if the ratio is low, less than unity, then there is little possibility of such a phenomenon occurring.

Several years ago, Duquesne Light Company installed a 130-kva series capacitor on a 4-kv distribution circuit and found that the capacitor caused a 225-horsepower 1,200-rpm 2,300-volt synchronous motor to hunt violently at no load. In this particular case, the most economical solution was to connect the motor to a 22-kv circuit through a step-down bank.

In the distribution circuit mentioned previously, the ratio of resistance to reactance was found to be about 4.0. However, in the Phillips–Crucible circuit and system ahead of it, the ratio of resistance (7.5 ohms) to equivalent reactance (12.0 ohms) up to the motor terminals with capacitor in service was

found to be the low ratio of approximately 0.6. No hunting is therefore expected.

Self-Excitation of Motors

Induction motors and synchronous motors which start as induction motors may fail to pull up to normal operating speed on starting after a series capacitor is installed on the circuit. This particular phenomenon is called "self-excitation." A motor which self-excites comes up to only partial speed on starting, and locks in at that reduced speed. At this reduced speed, the motor is unstable and large resonant currents flow.

Calculations and studies indicated that from a theoretical standpoint a minimum of 100 ohms in shunt with the series capacitor would be needed to prevent self-excitation when the 4,000-horsepower induction 514-rpm motor was started. These calculations are described in a companion paper.[1]

Resistor, Circuit, and Capacitor Losses

Load Division Through Resistor and Capacitor

If the 10,000-kva series capacitor is shunted with a resistor, a certain amount of load current will by-pass the capacitor and flow through the resistor, causing I^2R heat loss. Table I shows the calculated line amperes and the amperes calculated to flow through a 100, 200, 400 or 800 ohm resistor and the capacitor with a load of 28,000 kw at 87.5 per cent power factor.

Losses

In determining the annual kilowatt-hour loss of the line, capacitor and resistor, the customer's annual load factor was assumed at 40 per cent, which is the approximate average of the annual load factors at Crucible for the past seven years. Because of the squared function, the load factor of the losses is less than the load factor of the load. The approximate relation is that for a load factor of 40 per cent, the copper loss load factor is approximately 24 per cent.

Table II shows the I^2R line loss (both the maximum one-hour loss in kilowatts and the annual loss in kilowatt-hours) before the capacitor was installed, and after the capacitor was installed and shunted with a 100, 200, 400, 800 or an infinite ohm resistor.

Table II also shows similar resistor losses for each size of shunting resistor.

The capacitor has a loss of 1/3 of 1 per cent at rated load of 500 amperes. This loss is converted to an equivalent resistance at full load. The losses are therefore proportional to the square of the current flowing through the capacitor. The capacitor losses are shown on Table II.

Switching Equipment for Shunt Resistor

Table II shows that the resistor losses are quite substantial. These losses could be saved by switching the resistor into service only when the large 4,000-horsepower induction motor is started and when the line is energized.

Switching equipment was not provided because it was believed that the need for the correct resistor size should first be determined by tests. However, a preliminary scheme for switching consists of one 3-pole gang-operated 69-kv 600-ampere disconnecting switch with motor-operated mechanism. This switch could be operated by "carrier current" remote control equipment from the customer's motor room and Phillips Power Station.

Summary

The line current is reduced from 338 amperes to 308 amperes with the series capacitor in service but not shunted with a resistor, when customer's load is 28,000 kw at 87.5 per cent power factor. Table II points out that with the installation of the series capacitor (not shunted with a resistor or with the shunting resistor switched), Duquesne Light will save approximately 250 kw in maximum one-hour loss and 500,000 kwhr in annual losses, as compared with conditions with no capacitor. Table II shows that the total losses with the capacitor, with a 400-ohm shunting resistor or larger in ohmic value, is less than the line loss with no capacitor. Thus, voltage corrective equipment with the 400-ohm shunting resistor or larger is installed without increasing system losses.

On the basis of average system generating costs per kilowatt-hour, system diversity, and capital costs per kilowatt of generating capacity, the losses of 100- and 200-ohm resistors are such that it would be economical to install switching equipment in the resistor circuit to save the losses. For a resistor of 400 ohms and greater, the switching equipment cannot be economically justified.

Series Capacitor Test Program

While calculations indicate that subharmonic frequencies would be present in starting the 4,000-horsepower induction motor with the capacitor in service, there are certain factors that cannot readily be taken into account in calculations. Calculations usually indicate that a resistor of much lower ohms shunting the capacitor is needed than is actually required. Thus, it was expected that a resistor of a higher ohmic value than the calculated figure of about 100 ohms would be satisfactory. Because of this, 4 400-ohm 7,200-volt resistors were provided, as described in a companion paper,[1] with connections to give an immediate range of 100 to 400 ohms. A range of 400 to 1,600 ohms can also be obtained.

(B) Stator current before capacitor installation
(C) Rotor current with capacitor and 400-ohm resistor
(D) Stator current with capacitor and 400-ohm resistor

Motor Starting Tests

A test program was prepared which covered starting the motor with no capacitor and starting the motor with 100 ohms, 400 ohms, and infinite ohms shunting the capacitor, with a customer station load of 15,000 kva or more, and with no station load for each of the conditions.

Line Energizing Tests

The program also included the energizing of the 66-kv line from Phillips Power Station with bank magnetizing current only with no capacitor, with the capacitor in service shunted with a 100-ohm resistor, and without a resistor.

Meters for Test Program

An Esterline ammeter and voltmeter, and an oscillograph were installed at Phillips Power Station. Seven Esterline meters were installed at the customer's substation to record station load and 11-kv and 66-kv voltages. Six Esterline meters and an oscillograph were installed in the stator and rotor leads of the 4,000-horsepower induction motor and in the leads to an auxiliary power bank supplying a 1,000-horsepower synchronous motor-generator set.

Electrical quantities at Kennedy substation were not measured because of the difficulty of connecting instrument transformers. However, Veeder counters are permanent equipment on the gap by-pass switches to record switch operations.

Table I. Line, Resistor, and Capacitor Amperes With Various Shunting Resistors

Resistor Sizes	Crucible Load	Power Factor	Line Amperes	*Capacitor Amperes	*Resistor Amperes
Ohms	Kw	Per Cent			I
0	28,000	87½	338	0†	0
100	28,000	87½	313	310	42
200	28,000	87½	311	311	21
400	28,000	87½	309	308	10½
800	28,000	87½	308	308	5¼
None	28,000	87½	308	308	0

Results of Series Capacitor Tests

Motor Starting Tests

Motor starting tests were conducted as outlined, and the 4,000-horsepower motor came up to normal operating speed in all cases. Only the more important records are reproduced in the figures which follow.

Figure 6, curves *A* and *B* show the rotor and stator currents for normal motor starting without the series capacitor. Curves *B* and *C* show the rotor and stator currents for starting the motor with the capacitor in service, shunted with a 400-ohm resistor and with practically no plant load.

For the motor starting test without a resistor around the capacitor and with substantial plant load, the rotor and stator currents were normal and without evidence of other frequencies. However, when most of the plant load was dropped and the motor restarted from rest, subsynchronous frequencies were present. The subnormal frequencies caused two of the by-pass gaps to flash over on each of two phases of the series capacitor. When the gaps operated, the by-pass switches closed.

The gaps flashed over because at the subsynchronous frequency of about 5 cycles per second the ohms in the series capacitor are 12 times their 60-cycle value. Thus, since the gaps were set to flash over at a voltage corresponding to 1,000 amperes (60 cycles), only about 85 amperes of 5 cycle current were required to break down a gap.

Table II. Line, Resistor and Capacitor Losses

	Maximum Hour Kilowatt Loss	Annual Kilowatt-Hour Loss
Line Loss—No Capacitor	1,585	3,330,000
Line Loss—With Capacitor	1,360	2,860,000
100 Ohm Shunting Resistor	528	1,113,000
Capacitor Loss	13	27,000
Total	1,901	4,000,000
Line Loss—With Capacitor	1,345	2,830,000
200 Ohm Shunting Resistor	264	555,000
Capacitor Loss	13	27,000
Total	1,622	3,412,000
Line Loss—With Capacitor	1,325	2,781,000
400 Ohm Shunting Resistor	132	278,000
Capacitor Loss	13	27,000
Total	1,470	3,086,000
Line Loss—With Capacitor	1,320	2,780,000

Figure 8. Energizing Crucible and Midland unloaded banks (54,000 kva) with no capacitor, showing amperes per phase at 66 kv

Figure 9. Energizing Crucible and Midland unloaded banks (54,000 kva) with capacitor, and 100-ohm shunting resistor, showing amperes per phase at 66 kv

Figure 9. Energizing Crucible and Midland unloaded banks (54,000 kva) with capacitor and no shunting resistor, showing amperes per phase at 66 kv

Figure 7 is the record of quantities which were measured during this test. The rotor current record, even though it is from a high speed recording chart, gives evidence of some transient condition. The current records also give some indication when the gaps in the capacitor broke down closing the by-pass switches and when the by-pass switches reopened. The breakdown of the gaps possibly accounted for the motor coming up to speed.

Calculations indicated that the subharmonic frequencies would occur during the first 30 seconds. The motor takes 105 seconds to reach normal speed. Actual tests indicated that the condition did not take place until after the first 30 seconds. Oscillograph films used to record the tests were only eight feet long, and 30 seconds of record was the best that could be obtained; therefore, the subnormal frequencies were not recorded on the films.

Energizing Tests

Figures 8, 9 and 10 show an oscillograph record of the currents in the three phases of the Phillips–Crucible line as recorded at Phillips during the three energizing tests. It will be noticed that with a 100-ohm resistor shunting the capacitor, the initial inrush current seems to be damped out, as compared with the inrush current with no capacitor. With the capacitor in service and no shunting resistor, the energizing current is very erratic, and several of the gaps at the series capacitor flashed over. However, the steady-state current magnitude was of insufficient value to maintain the arc, and the gaps went out on their own account without closing the by-pass switches.

Summary

Motor starting tests with the capacitor in service and no shunting resistor and no other station load have indicated that a resonant condition exists. The capacitor, therefore, was shunted with a 400-ohm resistor at the end of the test and left in service. This 400-ohm resistor should also keep the gaps from flashing over in case of picking up the unloaded bank.

Future tests may be conducted to determine whether or not a 600- or 800-ohm resistor will be satisfactory for both motor starting and line energizing, since a higher value of resistor will reduce losses.

Discussion

E. C. Starr (Oregon State College, Corvallis, Oreg.): Many transmission engineers have followed the installation and testing of this series capacitor with keen interest. It was recognized that the large motor load involved presented special problems and we were anxious to learn the actual degree of resistance shunting required to produce successful operation under adverse motor-starting conditions. It now has been shown experimentally that this shunting resistor can be large enough to result in total circuit losses that are less than those existing with no capacitor and that the load voltage level and regulation have been improved greatly.

The conservatism of the engineers on this project in providing adequate shunting conductance to insure successful operation is appreciated by those of us who are thinking in terms of much larger series capacitors at higher transmission voltages. A questionable degree of success in this instance would have impeded progress in the development and acceptance of the larger units. The present highly successful application will facilitate the next step.

We are thinking not only of series capacitors for voltage improvement on short lines but particularly for load-limit improvement on long lines. In the present application, quick restoration of the capacitor after the protective device has flashed is not desirable, but in the long-line case, especially when multiple circuits are involved, immediate restoration after fault isolation is critically important. The ideal protective device for this service would be one which incorporates lightning-arrester characteristics. The excess voltage peaks only then would be clipped each half cycle and the capacitor would be restored to service within one-half cycle of the time of fault isolation.

A series damping resistor in the protective circuit designed to limit capacitor voltage to

safe values for maximum fault currents would further improve the performance. Local circuit oscillations during the short-circuiting operations would be damped effectively and the capacitor at no time would be completely removed from the circuit. Transient stability of the system would be improved substantially by both the high speed of capacitor reinsertion and the incomplete removal of the capacitor during faults, most of which are other than of 3-phase character.

In the present and similar cases, it appears that an adequate time delay of reinsertion built into the protective device might eliminate the need for a shunting resistor to control subsynchronous resonance during critical motor starting operations. With this delay, the capacitor would be short-circuited when resonance developed either by gap or by relay action and would not be reinserted until the motor had accelerated beyond the resonant speed.

It is generally understood but again should be emphasized that practical voltage improvement by series capacitors, as in the present case, can be obtained only when the load is definitely of lagging power factor, and when the over-all reactance-to-resistance ratio of the uncompensated circuit is considerably greater than unity.

A. G. Darling (General Electric Company, Schenectady, N. Y.): Since only a few installations of series capacitors have been made with the purpose of improving the voltage regulation caused by arc furnaces, the results of operation of an installation heretofore unreported, may be of interest and use to the industry.

Conditions governing the choice of characteristics of the capacitor will vary with each case. A close analysis of the circuit characteristics and loads as well as the amount of capacitors installed is essential to evaluate the results.

In 1939, some rather complete tests were carefully made on the series capacitor installation of the Braden Copper Company at Rancagua, Chile. The installation and tests were made under the supervision of A. J. Noraeger, chief electrical engineer, by his technical assistant, F. A. Canzi. So far as is known, this was the first attempt to offset rapid load fluctuation of arc furnaces by this method.

Generation of the Braden system in 1939 was in two hydroelectric plants of 47,000 kva total capacity stepped up to a transmission system of 66 kv to serve the general mining area with a 34.5-kv tapped line from two 5,110-kva transformers. The line runs 18 miles to the furnace and plant residential area at Rancagua. The furnace had disturbed the lighting voltages in this area. At the Rancagua Station, one set of main transformers serves the furnace transformers, and another serves the lighting and general shop loads. To correct the regulation of the furnace transformers by 34.5-kv series capacitors would have over-corrected the voltage applied to the lighting and general power transformer primary voltage. Therefore, series capacitors were selected which have capacitive reactance equal to the inductive reactance of the autotransformers supplying the 34.5-kv line and the line itself totaling 20 ohms. The line resistance is 10 ohms. The capacitors selected were standard 2,300-volt 15-kva units, 18 per phase in parallel totalling 780 kva 3-phase 60-cycles. A bypass contactor was relayed to shunt the capacitor at 275 amperes or 5,500 volts across the capacitor and insert the capacitor again when the current falls to 110 amperes.

The load at Rancagua consists of general load whose maximum is 2,000 kw at high power factor, a 1–1$^1/_2$ ton, 800 kva and two 3 ton, 2,000-kva furnace transformers each of which has current limiting reactors giving 35 to 40 per cent reactance on transformer base.

Low voltage shunt capacitors of 1,260 kva and a synchronous condenser of 2,350 kva are connected to the furnace transformer 6.9-kv bus.

The series capacitor is installed near the source end of the 34.5-kva line as better effect was anticipated.

On staged tests wherein the electrodes of the three furnaces were simultaneously shorted, the lighting voltage changed by 39 volts without the series capacitor and by 26 volts when the series capacitor was in service. This showed an improvement of 33 per cent. This simultaneous shorting of the three furnaces is possible but rarely, if ever, occurs under automatic electrode control.

Fast chart, recording meter records, and oscillographic records were taken with alternative operation of the synchronous condenser and the series capacitor when the two 3-ton furnaces were on rough and meltdown loads.

RESULTS OF OPERATION

Equipment in Operation				
Synchronous condenser	off	on	off	on
Series capacitor	off	off	on	on
Shunt capacitor	on	on	on	on
Kilovolts on 6.9-Kv Furnace Supply Bus				
Maximum	7.0	6.7	6.7	6.5
Minimum	6.0	5.8	5.8	6.0
Spread	1.0	0.9	0.9	0.5
Lighting Voltage				
Maximum	116	118	112	115
Minimum	101	106	105	105
Spread	15	12	7	10
Range of rates of change (Volts per second)	16–18	6–16	4–12	5–9
Variation in Illumination by Sight Meter				
Rough melt—foot candles	10–12		5–6	
Meltdown—foot candles	3		1	
Changes per minute	22–29		10–18	

The series capacitor reduced the amplitude of light intensity change to 1/2 and reduced the frequency of objectional changes in intensity to 1/4 or less than it was without the series capacitor.

Visual conditions were improved further

Figure 1. Braden Copper Company system in 1939. Reactances on 10,000-kva base

than the data given indicates as the number of small voltage changes, noticeable as light flicker, were reduced when the series capacitor was in service.

A shunting resistor was not used and no difficulty was encountered in magnetizing transformers or starting of motors or capacitors.

J. W. Butler (General Electric Company, Pittsfield, Mass.): It is gratifying to see the capacitor grow from a piece of laboratory equipment to a major tool at the disposal of system designers and operators in a period of about 20 years. It has been taking on larger and tougher jobs on systems in the last decade to a point where now it can rightfully take its place along with the transformer, circuit breaker, and generator. It is a credit to the application, design, and planning engineers connected with this project to be able to:

1. Sell the idea to their management.
2. Produce and operate successfully the equipment as planned.

I have been associated with capacitors and self-excitation of motors for some time and I can well appreciate the problem confronting the authors of this paper. I have tested in the laboratory and on field installations where these phenomena existed and also have done considerable analytical work on the subject, and I can certainly appreciate the authors' remarks to the effect that there are a lot of things that cannot be taken into account on the analytical work making the accurate prediction of operating results very difficult, if not impossible.

In viewing through an oscilloscope the motor current as the series capacitor ohms are increased distortions appear in the current long before an unstable run-away self-excitation current is obtained. In some set-ups it is only these stable wriggles that appear as the motor comes up to speed, while in other set-ups the circuit becomes unstable which causes the motor to vibrate, become noisy with rotor oscillations and continuous operation of the protective equipment. It is practically impossible to predict the difference between these two cases analytically, so obviously engineers have to play safe in making an application where calculations indicate the possibility of this difficulty.

In the case at hand, it is reported that with no resistor, subsynchronous frequencies existed and the motor experienced difficulty in coming up to speed, but with the 400-ohm resistor it performed satisfactorily, and this value was left in service. I have found that a very high value of resistance is tremendously more effective than infinite resistance, which suggests the possibility of operating this installation at a much higher ohmic value than the 400 arrived at. I understand that 1,600 ohms is obtainable by reconnection. I feel this value has a good chance of working, and if it does work the losses would be reduced to 25 per cent of their present value.

The success of this installation in general should give encouragement to engineers having similar bad voltage conditions. Many of the modern ore reduction processes impose severe requirements of power supplies and this type equipment should prove useful.

Leonard M. Olmsted (Duquesne Light Company, Pittsburgh, Pa.): The series capacitor described in this paper has been in service three months, and it may be interesting to have a preliminary report on its operation. This discussion presents the observations of several operating engineers and the authors of the paper, based upon a series of tests, inspections, and performance of customers' equipment.

The series capacitor has very satisfactorily demonstrated its effectiveness in reducing voltage dips, improving the unbalance in voltage and the general level of voltage. Before the capacitor installation, the large 4,000-horsepower motor tripped occasionally from under-voltage and voltage unbalance conditions caused by electric furnace operation. At times starting had to be delayed until furnace load was reduced.

As a result of the improved voltage, the Crucible Steel Company can take loads for short periods at off peak times considerably in excess of those formerly taken. There was some concern at first because these high loads were in excess of the rating of the line and of the capacitor. Thermal indicating meters installed in the line at its power input end, however, showed that the load lasted only a short time (less than 15 minutes), and occurred only two or three times a week.

Since the capacitor was installed, it has been taken out of service several times for inspection, first at rather short intervals and then at longer intervals. Five weeks have elapsed between the last two inspections. It was believed that inherent troubles in the capacitors themselves would show up rather early. As time goes on, it is hoped to schedule the routine inspections to six months or longer.

There have been minor operating difficulties as can be expected from a new installation. The troubles that have occurred are burned bellows and a few blown fuses on the individual capacitors. The burned bellows have been associated with one or more starts of the 4,000-horsepower motor during a period when the liquid starting rheostat was not allowing proper starting. This permitted a subsynchronous resonant condition to exist which was of sufficient magnitude and duration to damage the bellows operating elements in some of the by-pass switches. At the time this happened, the capacitor was shunted with a 400-ohm resistor which was considered satisfactory for all normal motor starting.

In order to guard against a repetition of damage to the switches in the event of future resonant conditions that may occur, a modification was made in the by-pass switches.

The capacitor fuses operated from overload and not from short circuit, probably during the resonant condition. This could happen because, as the protective gap flashes over, the capacitor discharges like a surge generator through the gap circuit. Several gap discharges could result in sufficient current magnitude to weaken the capacitor fuses.

The troubles that have occurred make it desirable to have some device to indicate whether the by-pass switches have operated and the approximate condition of the individual capacitor fuses without having to take the capacitor out of service. This problem is being studied at the present time and something will be done.

After the by-pass switches were modified, two additional motor starting tests were conducted with a 400-ohm capacitor shunting resistor and no furnace load. In each of these tests, the motor came up to speed in a normal manner.

Particular attention has been given to safeguarding service reliability. This radial line is the only supply to a large steel plant, and was designed with a high impulse level in an effort to provide reliable service. Eight service years without interruption from lightning and with only two cases of minor trouble have demonstrated the soundness of this design. Obviously the capacitor substation could not be permitted to impair this service record; it was designed to maintain the high impulse level and to permit the use of "hot stick" tools for maintenance without requiring a line outage. The selection and arrangement of pole-top switches lightning arresters and connectors reflect these requirements.

B. M. Jones: As referred to in the paper, we explored other methods for correcting this voltage situation, including the installation of synchronous condensers and switched shunt capacitors at the customer's plant, and a second line from our Phillips Power Station to the customer's plant. The selection of the 66-kv series capacitor was made after a thorough analysis of all factors, including installation and operating costs and carrying charges, as well as maintenance difficulties. Interestingly, the synchronous condenser installation required two medium size condensers so that the maintenance program could be carried on and still improve, to a partial degree, the customer's low voltage. This maintenance schedule is very interesting, and I will touch upon it only briefly. One 24-hour shutdown would be required once a year, and in addition an 8-day consecutive shutdown would also be required once a year. This may seem extreme to some of you, but our experience on large rotating equipment in steel mills indicated that this would be required.

Our management was not hard to convince, but did ask if this was the least overall expensive way of doing the job, and we had comparative figures ready to show that it was.

Another interesting installation of a series capacitor application for eliminating voltage fluctuation has just been made by the Lake Superior District Power Company, in connection with mine hoists. This was a 3,000-kva installation on a 33-kv line, and it is in the Gogebic Iron Mining Range in northern Wisconsin. This is described in the January 1948 issue of *Electric Light and Power*.

We feel very proud of our installation, and while we carried on negotiations ahead of time and consulted with all and sundry over the country who could help us, including Westinghouse and General Electric, the proof of the pudding is in the eating, and Figure 3 shows the corrective effect of the voltage schematically, and Figures 2 and 4 show the actual voltage chart before and after the series capacitor was installed.

However, I would like to say a word of caution here. Make a thorough investigation of your conditions, consult all who can help you, and read up all the literature you can find on the subject, including those

references listed at the back of the paper, and I believe that you can solve some of your voltage problems by properly applying series capacitors.

Starr questioned the need for any resistor shunting the capacitor, particularly if the protective devices were allowed to flashover whenever the motor did self-excite and no damage resulted to the protective devices. The probabilities are that the motor would not self-excite at every start but only at such times as the remainder of the plant load is very low. We have considered that if the protective devices were allowed to operate in lieu of having a shunting resistor, more frequent inspection of the capacitor overvoltage protective devices would be required, and fuses on the individual capacitor units might be weakened by frequent discharge of current through them. Furthermore, damage might be done to the motor should it be subjected on starting to frequent self-excitation, which causes the capacitor by-pass gaps to flashover.

The installation is now operating with a 400-ohm shunting resistor. We hope to make further tests in the near future to determine just how much higher we can raise this resistance. There are appreciable losses in this resistor being in service continuously, and the higher we raise this ohmic value, the less the losses are, and naturally we are interested in saving the company money wherever we can. (These comments also apply to Butler's discussion.)

We have laid out the installation so that circuit breakers for switching the resistor in and out can be installed in the future, but we feel now that the cost of the losses does not justify this installation, even at a 400-ohmic setting. The cost of the losses would have to increase very appreciably before such an installation could be justified.

Relative to Starr's comments on such an installation being applicable only where lagging power factor exists, we realized this. We also realized that the corrective effect diminishes as the lagging power factor approaches unity.

Darling's comments on a 780-kva 3-phase series capacitor in a 34.5-kv line in South America in 1939, for taking out some of the flicker caused by large electric furnaces—one 800 kva and two 2,000 kva—were very interesting. Here is another case where the series capacitor really has a field.

The reason for this installation was to take the flicker out of the residential lighting, whereas in our case that was secondary, and the main reason was to raise the voltage at a large industrial customer, as well as to reduce the flicker to this customer and elsewhere on this line, so that the improved voltage would be suitable for residential lighting

Butler's discussion was gratifying to us, and his experience over a number of years with this problem indicates to him that the increased distortions appear long before the unstable run-away self-excitation is obtained. Fortunately, we did not encounter any excessive vibration during these tests, but there was some slight vibration which, we feel, may have been caused by the conditions of the water rheostat in the secondary of the 4,000-horsepower motor, which conditions are being corrected by the customer

We were very glad to note that Butler feels so confident that a very high value of resistance is tremendously more effective than infinite resistance, and we hope soon to increase this 400-ohmic resistance to a higher value, although we are treading cautiously in this matter.

While Olmsted and I are employees of the same company, his comments relative to the operation of the series capacitor and associated apparatus are very apropos, even though it had been in service only a few months. We are always trying to reduce costs of capital investment, as well as operating expenses.

We are hoping to have very soon a visible device of some kind on this installation to indicate whether the by-pass switches have operated, and the approximate conditions of the individual capacitor fuses, all without having to take the capacitor out of service, as this is very undesirable. Subsequent to the presentation of this article, encouraging progress has been made on this problem.

Design and Layout of 66-Kv 10,000-Kva Series Capacitor Substation

G. B. MILLER
MEMBER AIEE

Synopsis: This paper describes the design and layout problems encountered in the construction of a substation for the largest series capacitor installation in operation to date. Companion papers[1,2] cover the application and equipment design of the series capacitor.

AT KENNEDY SUBSTATION, in October 1947, the largest series capacitor installation in existence and the first to be installed at 66 kv, was placed in commercial operation on the Duquesne Light Company's system, Pittsburgh, Pa. The substation was installed in the 14 mile Phillips–Crucible 66-kv transmission line. This line is of modern wood pole construction and was installed in 1940 to serve a large steel plant. The initial load was about 10,000 kva, and has since increased to approximately 40,000 kva. Electric arc furnaces are the principal load. Other major load consists of large synchronous motor generator sets and a 4,000 horsepower wound rotor motor.

Until recently the only load on this line was that of the steel plant. In 1947 a tap was connected to provide 10,000 kva service for the town of Midland, Pa. This increased load, plus a large proposed extension of the steel plant, made it imperative that some action be taken to improve voltage regulation and alleviate annoying voltage flicker produced by the electric arc furnaces. The flicker also affected the stable operation of the synchronous motor generator sets. Various means of correcting this voltage condition were considered and after careful analysis it was decided to install a series capacitor. Figure 1 shows the relative location of the capacitor in the transmission line. Figure 2 shows a schematic single line diagram of the substation.

Brief Description of Equipment

The series capacitor is composed of the capacitor proper, a shunting resistor, and a grounding switch. The resistor is connected in parallel with the capacitor to prevent low frequency resonance conditions when starting the 4,000 horsepower wound rotor motor at minimum plant loads. The resistor will also prevent, or damp out, a high inrush of low-frequency current which may exist when energizing the customer's unloaded transformer banks. The grounding switch is for discharging and grounding the series capacitor when taking it out of service.

The nominal current rating of the transmission line, in which the series capacitor is inserted, is 500 amperes. The capacitor was purchased to match this current rating.

The general characteristics of the equipment are

Capacitor

10,000 kva, three phase, 60 cycles
500 amperes continuous
750 amperes for 5 minutes
675 amperes for 30 minutes
Ohms to neutral: 14.4 + 0 per cent − 13 per cent, in accordance with National Electrical Manufacturers Association Standards
The nominal rating is 13.5 ohms.

Resistor

Composed of three single-phase units each having four–400 ohm sections. Provision is made for connecting at 100, 133, 200 and 400 ohms, with continuous current carrying capacities of 72, 54, 36 and 18 amperes respectively.

Each phase of the capacitor is contained in an outdoor weatherproof steel housing approximately 28 by 4 feet, by 12 feet high. Shipping weight, less capacitors, was 11,000 pounds. The installed weight is 25,000 pounds.

Each resistor is contained in an outdoor weatherproof aluminum housing approximately 20 by 4 feet by 10 feet high. It was shipped completely assembled and weighs 9,000 pounds.

Capacitor Details

The capacitor consists of three major units, one per phase. Each phase unit consists of 240–2,400 volt, 15-kva capacitors, filled with Askarel, each with its own protective fuse. Each unit is arranged in three groups of 80 capacitors connected in parallel with the three groups connected in series. On the basis of 13.5 nominal ohms, the assembly represents an in-service capacitance of 197 microfarads and produces 6,750 volts drop at 500 amperes.

Each group of 80 capacitors is protected by a heavy-hooded graphite safety gap, which is automatically shunted out of service, in case of discharge caused by overvoltage across the capacitor bank, by means of a self-actuating contactor operated by a thermally actuated vapor-filled bellows. This protective equipment is mounted inside the capacitor housing.

Paper 48-56, recommended by the AIEE transmission and distribution and substation committees and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 10, 1947; made available for printing December 19, 1947.

G. B. MILLER is senior engineer in the electrical engineering department of the Duquesne Light Company, Pittsburgh, Pa.

Figure 2. Schematic single line diagram

Figure 3 (right). Schematic longitudinal section of phase unit

The capacitor cubicles are mounted on 69-kv post insulators and operate at 38,000 volts above ground. Fifteen kv roof bushings are provided for line connection.

Shunting Resistor Details

The resistor housing in general matches the appearance of the capacitor, with the exception that it has a galvanized steel framework with aluminum sides. Aluminum was provided to eliminate heat damage to the housing. It is open at the top and bottom to provide adequate ventilation. The openings are covered with screens to keep out rodents and birds.

The resistor cubicles are mounted on 69-kv post insulators and are equipped with 15-kv bushings for connection to the line.

Each resistor phase unit is designed to operate continuously with 7,200 volts impressed across it. It consists of resistor groupings that can be connected at various values of resistance from 100 to 400 ohms. At present the resistor is connected for the 400-ohm value. By minor internal changes it will be possible to reconnect the resistor for higher values, up to 1,600 ohms maximum, if it is later decided to operate in excess of the 400-ohm value.

Each phase unit of a capacitor and shunting resistor was installed in line, and about four feet apart, on a flat monolithic concrete foundation about 50 by 5 feet by one foot thick. Piers extending two feet above the foundation were installed to

Figure 8. Interior view of resistor housing

elevate the equipment to about maximum winter snow level height, and also to prevent weeds from short-circuiting the 69-kv supporting insulators.

Figure 3 shows a schematic arrangement of the resistor and capacitor housing. Figures 4 to 8 show this equipment.

Grounding Switch

To effectively discharge the capacitors after isolating them from the line, a 3-pole 69-kv remotely operated shunting disconnecting switch was installed. When closed, it shunts the capacitor and resistor, and grounds their housings. Its operation is controlled from outside the fence. The switch and operating mechanism is shown in Figure 9.

Substation Site and Arrangement of Equipment

The substation is located on 1.4 acres of gently sloping farm land, adjacent to an improved highway, 4.8 miles from the customer's end of the transmission line. The site lies directly under the transmission line. Figures 10 and 11 show a schematic layout and general view of the substation.

The series capacitor phase units are located on 15-foot centers. The concrete foundation slabs supporting them are unique, as no piers or footers are used below the frost line. These slabs are at ground surface elevation and set on nine inches of crushed slag. This construction allows for expansion of the ground due to freezing and will permit seasonal movement of the equipment. This, however, is not considered to be objectionable as each phase unit is entirely independent of the others and free to move.

No provision was made for station service. However, a distribution line runs nearby and could be made available if it is required later. There is no apparent need for it, as there are no relays, control, light or heating.

Switching Equipment

The 66-kv switching equipment required for placing the equipment into or taking it out of service consists of three 3-pole 600-ampere 69-kv air break disconnecting switches.

At the inception of this job it was thought the main by-pass switch would have to be a 69-kv oil circuit breaker of 1,000,000 or 1,500,000 kva interrupting

Figure 9. Ground switch in closed position

Note the operation of switch has permitted the gate at the left to open

capacity. However, before deciding on this, a factory laboratory test was made to determine if the charging current to be encountered could be safely broken with a horn gap air break switch.

These tests consisted of opening and closing a 15-kv air break disconnecting switch in a 20-kv test circuit with a series capacitor connected in shunt with it. The series capacitor consisted of 80–15-kva 2,400-volt capacitors connected in parallel. This arrangement of capacitors will pass 500 amperes with 2,400 volts impressed across it. The arcing horns of this switch, after twenty operations, did not show excessive burning.

These tests were performed at the same current value, with equipment and line voltages at approximately one-third of that proposed for the 10,000-kva series capacitor. The result of these tests indicated that a 69-kv air break switch would be satisfactory.

The full complement of switches—that is, the by-pass switch, the input switch, and the output switch were installed on wood pole structures approximately 28 feet high. They are operated manually from geared operating handles located near the ground. To facilitate maintenance of the switches without circuit interruptions, hot-line connectors were installed at the switch terminals.

During the course of test operations, conducted prior to cut-in, these switches were operated several times. All of the operations were very satisfactory, with the exception of the first time the by-pass switch was opened slowly with the capacitor in service. The result was a rather thick arc, which was drawn out from 12 to 15 inches in length before it blew out. The load current at this instant, so far as could be ascertained, was approximately 360 amperes. After this the switches were opened more rapidly and the amount of arcing on the by-pass switch was considerably less. There was no arcing at any time on the input switch. The arcing on the output switch never exceeded six to eight inches in length and was very thin.

These operations demonstrated that air-break switches are adequate to break charging currents of a capacitor bank of this size. Therefore, a considerable amount of investment was saved by not having to install a circuit breaker in the by-pass switch position.

Safety to Personnel

Safety to personnel is provided by:

1. Enclosing the capacitors and resistors inside a fence. This fence is 25 feet inside the one enclosing the entire installation. Both are 10 feet high with barbed wire at the top.
2. Key interlocks insuring the proper sequence of disconnecting switch operation.
3. A mechanical gate interlock which prevents anyone from entering the inner fence, where the capacitors and resistors are located, before the grounding switch is closed.
4. Grounding grid of low resistance.

The schematic layout shown in Figure 10 embodies the first three foregoing items. Figure 12 shows the mechanical gate interlock.

Ground Resistance

An attempt was made in the design of the grounding grid to limit the ground resistance to approximately one ohm. Sample ground resistance readings, taken at the beginning of construction, indicated that a grounding grid constructed of a reasonable number of ground rods would probably develop a resistance of 2.3 ohms. The resistance of the transmission line grounding grid taken on the same day was also 2.3 ohms.

The two grounding grids were tied together to produce low ground resistance. It was expected that 1.15 ohms would be produced by the combination. Actually, the resistance obtained was 0.65 ohm and somewhat better than anticipated. This reading was taken during wet weather. Dry season conditions probably will give a higher resistance, however, it is expected the value will not exceed the one ohm figure.

Station Impulse Level

The 66-kv transmission line being of wood construction, with insulated wood guys and grounded overhead shielding wires, has impulse insulation far in excess of the station equipment insulation. In order to protect the station equipment from impulses or surges entering the station, both lightning arresters and control gaps have been installed. In addition, overhead shielding wires have been installed over the equipment area and tied into the transmission line shielding wires. These shielding wires can be clearly seen at the top of the four high poles in Figure 11.

The arresters are rated at 73 kv and are of the line type porous-block construction, consisting of three 25-kv units in series. The control gap electrodes are set at 11-inch spacing. All station equipment, including the control gaps and disconnecting switches, have 69-kv heavy-duty station type insulators.

Figure 13 shows the various impulse levels of the station insulation. The arresters should operate first. In event they fail, the control gaps arc over and provide back-up impulse protection to the station equipment insulators. The arcing over of the gaps will cause the line to be tripped out on short circuit back at the Phillips station. Seven 10-inch line type suspension insulators are installed in each insulator string at the substation, as compared to six insulators plus five feet of effective wood on the transmission line.

Continuity Tests

To safeguard the possibility of installing any defective capacitor units, the entire number, 720 in all, were tested in the company's laboratory at 75 per cent of the standard National Electrical Manufacturers Association test. Several were found defective, indicating that this additional precaution was worth while.

After the capacitors were installed in the field, the individual fuses were checked for continuity. Only one or two defective ones were found. An over-all continuity test of each phase unit was made prior to being cut-in. A gasoline engine generator was used for this purpose. Measurement at 60-cycles 115-volts showed the capacitive reactance to range from a minimum of 13.3 to a maximum of 13.6 ohms, or very near the expected nominal value of 13.5 ohms.

The safety gaps which protect the capacitors from overvoltage were checked and set in accordance with the manufacturer's recommendation.

A continuity test was also given the shunting resistor prior to cut-in.

No Discussion

A Unique Application of the Wheatstone Bridge to High-Speed Train Braking

C. M. HINES
MEMBER AIEE

Synopsis: This paper describes a method for indicating to the locomotive engineman the condition of the circuits controlling the electropneumatic brakes which are now in widespread use on high-speed passenger trains. The apparatus consists of a Wheatstone bridge so arranged as to insure the operation of the bridge itself as well as to indicate the condition of the electropneumatic brake circuits. Calibrated dials indicate the number of vehicles in the train. This equipment is proving to be a useful tool in making terminal tests, and assist in determining the location of any change of resistance of the train line wire circuits which may occur. It also provides a convenient means for indicating to the engineman while en route, any change which may occur in the train line circuits. All parts of the equipment are designed to provide the ruggedness essential for long life on locomotives.

THE general public is no doubt unaware of the fact that the pneumatic brakes on most high-speed trains are normally controlled electrically with pneumatic control standing by in reserve. The term high-speed trains as used here applies to passenger trains running at speeds in excess of seventy-five miles per hour. The advantages of this type of electrical control have been recognized for many years, the first tests of such a brake being made in 1887. General acceptance did not occur until recent years, the modern form of the electropneumatic brake having been first applied to the early zephyr trains in 1933. A full description of this type of brake and the advantages accruing from its use, are covered in a previous paper.[1]

Since 1933 most high-speed trains have been equipped with electropneumatic brakes. Figure 1 indicates the essential elements of the present electropneumatic brake system. A pneumatically-operated master controller is equipped with contacts which supply energy by means of train line wires to application and release magnet valves, one pair being on each vehicle. It will be noted that all application magnets are in parallel and all release magnets are in parallel, a common return being used for both sets of magnets. When an electropneumatic brake application is made, movement of the brake valve handle introduces air under pressure to the chamber on the left side of the master controller, Figure 1, the pressure being proportional to the angular movement of the brake valve handle. The diaphragm of this chamber moves the lever controlling the contacts to the right, closing both contacts, and thus energizing both the release and application magnets throughout the train. Energizing the release magnets results in closing off the brake cylinders from atmosphere. Energizing the application magnets causes air under pressure to be admitted to the brake cylinders. At the same time, air at corresponding pressure is admitted from every vehicle to a pipe called the straight air pipe. This pipe is connnected to the right-hand chamber of the master controller. When the pressure in the straight air pipe and the chamber becomes equal to the pressure in the left-hand chamber, the lever moves to the left, but only a sufficient amount to open the contact which controls the application magnets. This halts the build-up of brake-cyclinder pressure at the value demanded by the position of the brake valve handle. The magnet valves control brake cyclinder pressure indirectly by means of a relay valve as shown in Figure 1.

With the preceding explanation of the circuits involved in the present electropneumatic brake system, it becomes apparent that it is desirable to have some means for indicating to the engineman any change which may take place in the condition of the circuits controlling the magnet valves throughout the train. The usual automatic air brake is always

Figure 1. Essential elements of electro pneumatic brake system

available and may be made operative by moving a lever on the brake valve. If sufficient time is not available to shift this change-over lever, an emergency brake is available simply by moving the brake valve handle to its extreme applied position. Since the usual form of brake application requires only a service application, practical operating experience indicates the desirability of informing the engineman of any change in the condition of the electropneumatic brake circuits, in order that in advance of a brake application he may change to the automatic air brake, and thus avoid the use of the emergency brake.

In considering a means for thus indicating the condition of the electropneumatic brake circuits the following tentative requirements were made as presenting an ideal solution:

1. All equipment for checking should be on the locomotive.

2. Because of the large number of passenger cars now in service with the electropneumatic brake, no change in car wiring should be required.

3. The equipment must be designed to operate satisfactorily with trains varying in length from 1 to 24 vehicles.

4. The equipment must operate satisfactorily over a wide range of voltage, the limits being from 58 to 80 volts.

5. The equipment must be sufficiently rugged to operate satisfactorily on a locomotive, long life and a minimum of maintenance being essential.

6. No power supply other than that used on present locomotives should be required.

7. The equipment must indicate continuously in advance of a brake application the condition of the electropneumatic brake system.

8. The indication means must be safe in that any failure of the equipment used for checking should provide the same indication as a failure of the electropneumatic brake system.

9. The checking current flowing through the magnet valves must be sufficiently low to insure against false operation.

With these requirements in mind, a system was devised which fulfills them. After making tests with numerous methods, it was finally decided that the use of the Wheatstone bridge was the solution. This old standby presents a ready means for accurately measuring the resistance of the magnet valves and the train line wires which control them, and so could be used to indicate any change in resistance resulting from open circuits or short circuits. The disadvantage of using the Wheatstone bridge lies in the fact that a null indication represents a balanced condition. Therefore, a fault such as an open lead to the galvanometer in the Wheatstone bridge would indicate a balanced condition, and a fault in the brake system would not be detected.

One unique feature of the system finally adopted lies in the means for converting the Wheatstone bridge into a device which checks its own operation as well as indicating any change in the condition of the circuits whose resistances are being measured. Figure 2 shows schematically the circuits involved in the system and all devices are shown in the de-energized position, it being assumed that the battery supply is open.

Two bridges are used, one for checking the application wire circuits and the other for checking the release wire circuits. The galvanometer usually associated with the Wheatstone bridge is replaced by a relay. This relay does not have to be a delicate instrument as will be shown presently. In addition to detector relays Y and Z, three additional relays are used for controlling the bridges. Relays W and X are used to alternately short circuit one of two arms of each bridge. The third relay V is of the polarized type in that the position of its contacts is controlled by the direction of current flow through the coils. The contacts of this relay control the W and X relays to select which one is operated. The sixth relay in the system, relay T, is used to disconnect the circuit checking equipment from the application and release wires during a brake application and to indicate that the brakes are applied. The seventh relay U controls the light indication or other means to warn the engineman of faulty circuits.

The sequence of operations is as follows: one of the time-delay relays, W or X, is first energized, short circuiting one arm of each bridge, and thus providing a large degree of unbalance to insure energizing detector relays Y and Z. The time-delay relay then becomes de-energized, and the detector relays can release, provided there is no unbalance of the bridges sufficient to hold either relay energized. This completes one half of the operating cycle. The polarity relay V is controlled by the action of the detector and time-delay relays, and its contacts select which of the two time-delay relays is to be energized. If during the first half cycle the

Figure 3. Relay cabinet

W relay is energized, thus placing a short circuit across the upper-right hand arm of each bridge, then during the second half cycle the X relay becomes energized, placing a short circuit across the lower right-hand arm of each bridge. It can be followed readily that if at any time a change in resistance takes place, whether it be a decrease or an increase, the Y or Z relays, or both, will be held energized when the short circuit is removed from the arms of the bridge, provided the change in resistance is such that the direction of current flow through the detector relays is not changed. This may occur during either the first or the last half of the complete cycle depending on the direction of unbalance. It can also be seen that the amount of unbalance caused by the change in resistance need be great enough only to hold the detector relay energized. The detector relays Y and Z as explained previously, may be rugged devices and they are particularly designed to have a low drop out with respect to the pick-up current.

Sensitivity to change in resistance can be made as desired. For the type of service being described, it is felt that detection of changes of 10 per cent are adequate, and that higher degrees of sensitivity would result in unnecessarily switching from the electropneumatic brake to the automatic brake with the consequent loss of the advantages of the former system. Therefore, the components of the circuit checking equipment have been designed to indicate a change in resistance of 10 per cent.

As relays W and X are alternately energized, relay U receives pulses of current to hold it energized, it being a time-delay device so as to bridge the time between pulses. If for any reason these pulses cease, relay U will become de-energized and the green indication normally seen will be changed to red.

If a brake application is made, the white light will become energized, provided the electropneumatic brake circuits, as indicated by the checking circuit equipment, had previously been intact. If a brake application were made with the red indication showing, the red light would continue to be energized.

The relay cabinet housing the control equipment is shown in Figure 3. Calibrated dials are used with the adjustable rheostats which form the upper right-hand arm of each bridge and serve to indicate the number of vehicles in the train. Since most of the faults occur in the jumper connections between cars, these calibrated dials serve a further purpose in that they are of considerable aid in locating the source of trouble. Figure 4 shows the light-indicating unit mounted in the locomotive cab within view of the engineman.

When initially taking control of the train, the engineman makes an electropneumatic brake application and the train is inspected to insure that brakes apply properly throughout. This is an indication that the electropneumatic brake wiring is intact and functioning as intended. The number of vehicles in the train must be known to the engineman. If the train consisted of three locomotive units and twelve cars, a total of fifteen vehicles would be used in setting the rheostats. The dials of the rheostat knobs are calibrated from one to twenty-four vehicles. The engineman, after determining that the electropneumatic brake is functioning properly and knowing the number of vehicles in the train, can then proceed to place the circuit-checking equipment in operation. The on-off switch to the left of the lights must be moved to the "on" position and both rheostats should be turned so that the proper number of vehicles on the dial is opposite the indicator for each rheostat. With both rheostat dials so set, the three-position toggle switch to the right of the lights is moved and held to the "up" position. This prevents the pulsing action of the relays and at the same time inserts a milliammeter in series with the corresponding detector relay. The power switch and three-position toggle switch are omitted from Figure 2 in order to simplify the circuits. The rheostats should then be readjusted until each milliammeter reads zero. This insures that both bridges are balanced. The three-position switch should then be pulled to the "down" position until the green light is energized, after which it may be released and it will automatically assume the center position. The calibration of the rheostat dials is merely an approximation and the milliammeters are used to insure accurate balancing of the two bridge systems. Nevertheless, the calibration on the dials will serve to indicate to a rather close extent the number of vehicles in the train, and if there is any large variation between the dial settings and the actual number of vehicles in the train, a fault in the train wire system is indicated.

Figure 4. Indicating light panel

To locate such a fault let us assume that in the 15-vehicle train the rheostat dial must be set to 12 to obtain a balance for the application wire. This indicates a faulty connection between the 12th and 13th vehicle, and that the poor connection must be in the application wire. If both rheostats register 12 vehicles, instead of 15, the fault might be in both the application and release wire, in the common return wire, or in all three. This means of fault location is applicable only if the fault is an open circuit existing in the plug connectors or jumper wires between cars. Experience has proved that most faults in the electropneumatic brake system are of this nature and consequently this method of fault location may be of considerable practical value from the standpoint of maintenance.

No attempt has been made to cover fully the circuit checking equipment in detail. A number of refinements vital to this particular application would be of little general interest. However, it is believed that the preceding information is insufficiently clear to give a general understanding of a new method for indicating change from a balanced condition. It can be used with any type of bridge circuit. The method is one which checks its own integrity, and which lends itself to applications demanding rugged apparatus, long life, and a minimum of maintenance.

Design and Protection of 10,000-Kva Series Capacitor for 66-Kv Transmission Line

A. A. JOHNSON
MEMBER AIEE

R. E. MARBURY
FELLOW AIEE

J. M. ARTHUR
ASSOCIATE AIEE

Synopsis: To correct for voltage regulation and light flicker on the 66-kv line supplying arc furnace and steel plant load, a series capacitor of 500 amperes continuous rating and 13.5 ohms was installed. This series capacitor was built with three groups of standard 2,400-volt 15-kva capacitor units connected in series per phase with each group being protected by its own by-pass gap and automatic switch. This is the largest and the highest voltage series capacitor so far installed.

THE Duquesne Light Company supplies the Crucible Steel Company at Midland, Pa., with electric service over a 66-kv 3-phase 60-cycle transmission line from the Phillips Power Station. To correct for undesirable voltage regulation and excessive voltage flicker caused by arc furnace load at the steel plant, the Duquesne Light Company decided that series capacitors would be applied to the 66-kv transmission line. Series capacitors are fundamentally fitted for this type of application because they have inherently instantaneous correction in reducing the range of voltage regulation and reducing light flicker. A series capacitor of 14 ohms having a normal current rating of 500 amperes was found to provide the necessary correction.

Paper 48-57, recommended by the AIEE transmission and distribution committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 10, 1947; made available for printing December 15, 1947.

A. A. JOHNSON is central station engineer, R. E. MARBURY, manager, capacitor section, switchgear control engineering department, both with the Westinghouse Electric Corporation, East Pittsburgh, Pa. J. M. ARTHUR is development engineer with the Duquesne Light Company, Pittsburgh, Pa.

To obtain the 500-ampere current rating and the required ohms, it was decided that standard 2,400-volt 15-kva capacitor units would be used and properly grouped. Using these standard units requires three groups in series per phase to obtain the desired ohms with a sufficient number of units in parallel to obtain the current carrying capacity of 500 amperes. By using a sufficient number of standard 2,400-volt units to obtain the 500-ampere continuous current rating per phase, the nominal ohms per phase would be 14.4.

Rating of Series Capacitor

Several factors have to be considered in determining the rating of a series capacitor.

1. Maximum continuous working current—500 amperes (except following a period during which the capacitor has been out of service when the ambient temperature has been below 0 degree centigrade, in which case, the capacitor current should not exceed 350 amperes until the capacitor warms up to 0 degree centigrade). The time required for the capacitor reactance to return to normal after being at temperatures below 0 degree centigrade is given in the following tabulation:

Initial Capacitor Temperature	Time in Minutes
−10 degrees centigrade	5
−20 degrees centigrade	30
−30 degrees centigrade	104

2. Maximum short time current.

Current	Time
500 amperes	Continuous
675 amperes	30 minutes
750 amperes	5 minutes

Short time overloads which may occur during normal operation of the series capacitor should not exceed 750 amperes, as currents greater than 750 amperes will approach the zone of operation of the short circuit protective device which is set for a nominal voltage corresponding to approximately twice the continuous current rating. However, overloads between 500 and 750 amperes may be permitted for the times given in the foregoing tabulation.

3. Maximum permissible fault current—5,000 amperes. This limitation is determined by the protective devices.

4. Capacitance ohms—nominal 14.4 minus a maximum of 13 per cent, actual ohms 13.5.

5. Line voltage—66 kv.

6. Rating of individual capacitor units—2,400 volts.

7. Rating of individual capacitor units—15 kva.

8. Line frequency—60 cycles.

Figure 1. Series capacitor housing for one phase ready for shipping

Design of the Series Capacitor

The capacitor equipment for each phase of the 66-kv circuit consists of a structural steel housing 28 feet long, $9^1/_2$ feet high, and $3^1/_2$ feet wide. This housing has 240 15-kva 2,400-volt type *FP* Inerteen capacitor units. The housing has three tiers, each containing 80 capacitor units. The 80 units on each tier are connected in parallel with individual fuses for each capacitor. The

Figure 2. Special gap for protecting series capacitors

three groups of 80 units are connected in series to form the series capacitor for one phase of the 66-kv circuit.

Each housing containing 240 capacitor units is supported on eight 69-kv post-type insulators. One insulated roof bushing provides for the 7,200-volt insulation while the housing forms the other terminal. The insulation to ground for the housing and all of the series capacitor units is provided by the 69-kv insulators between the housing and ground.

A grounding switch is provided for shorting the series capacitor and grounding it so as to protect the operator from charges on the capacitor and accumulated static charges on the housing. This grounding switch is interlocked with the main by-pass and the isolating disconnect switches. These devices are discussed in a companion paper.[2]

Design of Capacitor and Protective Device Housing

The outdoor series capacitor equipment consists of the capacitor compartments together with a protective device compartment assembled on a structural steel base and covered with a formed-sheet roof with provision for roof entrance bushings. Flexible braided connectors and horizontal and vertical bus bars are used for making connections between capacitors, protective devices, and roof entrance bushings.

The capacitor compartments and the protective device compartments including the doors are constructed of structural steel angles and formed sections of 1/8 inch thick steel welded together to form a rigid and self-supporting structure. The doors have concealed hinges and are provided on each side of the housing to permit ready access to the capacitor units and the individual capacitor fuses. The capacitor compartments have three shelves each arranged for supporting two rows of indoor capacitor units. The bottom of each capacitor compartment is covered with perforated sheet steel, and the side walls near the roof have screened ventilators to provide adequate ventilation. Figure 1 shows the complete series capacitor housing for one phase ready for installation.

Protection of Series Capacitor Against Overvoltage Accompanying Line Faults

Gaps

The voltage rating of the series capacitor was determined by the required voltage correction on the basis of the continuous working current of 500 amperes and the use of standard 2,400-volt units, as mentioned previously. This permits a maximum current loading of 1.5 times rated current or 750 amperes for 5 minutes to take care of short time overloads and the application of a parallel gap for voltage protection set above the voltage corresponding to 1.5 times rated current. The parallel gap protection is provided for each of the three groups of 80 capacitor units and limits the voltage which may appear across the series capacitor to approximately double the continuous rating of each group or about 4,800 volts.

Figure 3. Time-current curve of special gap based on permissible temperature rise

The gap protection consists of a gap designed for low arc drop and is designed in such a manner that arcing can take place without restriking, thus effectively protecting the capacitor if the gap has broken down. The flow of current through the gap also passes through a thermal element which initiates the closing of a switch which by-passes both the gap and the capacitor units, thus limiting the heating of the gap. Once the gap is by-passed by the switch, current ceases to flow through the thermal element and its temperature returns to normal. As the thermal element cools off, the by-pass switch is opened and the series capacitor is restored to service.

The gap is shown in Figure 2 and consists of a recessed upper electrode thermally loaded with a heavy metal casting. The lower electrode extends into the recess and the arc takes place at the top space provided for that purpose. Figure 3 shows the time-current working range of the gap based on a permissible safe temperature rise.

By-Pass Switch for Each Gap

Initially, consideration was given to the use of a 69-kv oil circuit breaker to by-pass all of the capacitor units in all three phases in the event of a gap flashover on any phase which was sustained. Such a circuit breaker is expensive, requires extra space and maintenance and, therefore, was not a desirable solution to the

Figure 4. By-pass switch showing the contacts and the operating bellows

Figure 5. Time-current characteristics of the bellows-operated by-pass switch

problem. By providing a parallel gap for each of the three groups of 2,400-volt capacitors on each phase, a very simple bellows-operated by-pass switch was applied across each gap as mentioned before. Thus, the undesirable 69-kv by-pass oil circuit breaker was eliminated by applying nine small, simple, rugged switches. This scheme is applicable because high-speed restoration of the series capacitor to the circuit after a by-pass switch closure is of minor importance, particularly when it is realized that these switches will very seldom be required to operate.

A by-pass switch is shown in Figure 4. It contains a toggle mechanism actuated by a special design stainless-steel bellows containing volatile liquid sealed after the removal of air. At all ambient temperatures, the bellows contracts with a force which is able to open the switch when forced into the closed position and released. A current flow through the bellows causes the contraction force to disappear due to vapor pressure which builds up high enough to cause the bellows to expand and close the switch. The closing of the switch terminates the flow of current through the bellows but the switch remains closed until sufficient condensation takes place within the bellows to develop the required contraction force to reopen the switch. Figure 5 shows the the time-current characteristic of the switch. Figure 6 shows the scheme of operation and the approximate steady-state temperatures for opening and closing operations. The actual bellows temperature exceeds these values due to overshoot to a degree dependent on the magnitude of the current and the time lag of the mechanism.

Each group of 80 capacitor units in the series capacitor is directly protected by the parallel gap. The main purpose of the by-pass switch is to limit the duration of the arc within the gap. However, another important purpose of the by-pass switch is to restore the series capacitor to the circuit if the gap should be flashed over due to transient voltages of any kind.

The three protective devices which include the gap and the by-pass switches for the three groups of 80 capacitors per phase are placed in the front of the housing and supported on 7,500-volt insula-

Figure 6. Scheme of operation of bellows-operated by-pass switch showing the approximate steady-state temperatures for closing and opening operations

tors. The housing for each phase is the same. The protective devices described have the advantage of requiring no external power source. The advantage of the bellows-operated by-pass switch lies in the fact that the bellows current elements are not inductive and operate over a wide range of current. Where the possible fault current is greater than 2,500 amperes, as in this case, the bellows is operated by means of a saturating current transformer which limits the current through the bellows to 2,500 amperes for fault currents in the line up to 5,000 amperes. Figure 7 shows the time-current characteristic of the current transformer and bellows switch combination. At the low current range, the current through the bellows is stepped up; and in the medium range, the ratio is about one to one. At the high currents, the bellows current is limited to a safe value for the bellows. Since each group of 80 capacitor units is protected separately by self-contained protective devices, the protective devices operate independently as required.

Protection Against Overload

Since the normal line current is well within the rated current of 500 amperes; and since the load currents are under frequent observation by operating personnel, no special provisions were made to by-pass the series capacitor in the event of prolonged overloads. Overload protection, if desired, can be obtained at the source end of the 66-kv feeder by putting in an alarm device which will indicate prolonged loading in excess of the rated current value of 500 amperes.

Failure of an Individual Capacitor Unit

Individual fuses are provided on each capacitor unit which will automatically disconnect a unit that might become short circuited internally. Figure 8 shows the time-current characteristic of each fuse. The rated current through each capacitor unit is 6.25 amperes. This type of fuse protection is ample because of the large number of capacitor units in parallel. The operation of one or two fuses will have little effect on either the voltage on the capacitors or the total reactance of the entire installation.

Figure 7. Time-current characteristics of the saturating current transformer and bellows-operated by-pass switch combination

Protection Against Resonance

The possibility of subsynchronous resonance under certain conditions of load and motor starting is well known in connection with series capacitors. It is, therefore, common practice to stabilize series capacitors by placing in parallel with them a resistor unit of suitable ohms. The effect of the parallel resistor is to either prevent or damp out subsynchronous resonance associated with motor starting and magnetizing current on power transformer banks. It also damps resonance at any frequency.

Each phase of the series capacitor is shunted by a resistor which may be set for several values of ohms between 100 and 400 ohms. The resistor unit has a thermal rating for continuous operation at any resistance value.

Determination of Shunt Resistor Ohms

As stated before, a series capacitor is very effective in improving voltage conditions but motor starting may cause subsynchronous resonance conditions. To prevent these undesirable operating conditions, a resistor of proper ohms in parallel with the series capacitor may be required. Such motor difficulties have been experienced on smaller series capacitor installations and are known as self-excitation where the motor rotor locks in and rotates at some speed considerably lower than normal speed. When this happens, excessive subsynchronous frequency currents will flow. The frequency of the subsynchronous current corresponds to the resonant frequency of the entire system when viewed from the rotor of the motor involved. Many factors determine whether or not a given motor will lock in at some subsynchronous speed when it is started.

1. Speed of acceleration.
2. Other loads in parallel with the motor.
3. The power factor of the parallel load.
4. The type of starting device used.
5. The WR^2 of the motor and its load.

At Crucible Steel Company, there are in operation several large induction and synchronous motors. To determine beforehand whether any or all of these motors are susceptible to self-excitation after the installation of the 10,000-kva series capacitor, an extensive study of all known theories and formulas on the phenomenon of self-excitation was made.

The largest motor involved at Crucible is a 4,000-horsepower wound rotor induction motor having a very large flywheel. This motor drives two d-c generators. The motor when started accelerates at a very slow rate and, therefore, it is questionable whether or not it will come up to proper operating speed if the series capacitor has no shunting resistor.

It became apparent, after some investigation, that all of the larger motors and especially the 4,000-horsepower induction motor at Crucible might self-excite after the installation of series capacitor if no resistor was provided. Because of the great need for solving the self-excitation problem before it occurred at Crucible, E. R. Whitehead developed self-excitation equations along lines suggested in an AIEE paper by C. F. Wagner.[4] From these equations, it is possible to tell approximately the amounts and power factor of loads needed at Crucible to prevent self-excitation of motors. It is also possible to determine the amount of shunt resistance to be placed in a parallel with the series capacitors to prevent the self-excitation of a given motor with no other load involved. This method gave for the 4,000-horsepower motor a required minimum parallel resistor of approximately 90 ohms.

The system impedance from the generated voltage on the Duquesne Light Company system to and including the 4,000-horsepower motor at the steel plant were set up on a calculating board and studied with various applied frequencies. The characteristics of the load, the motor and of the entire transmission circuit, and the magnetizing current of the trans-

Figure 12. Resistor for operation in parallel with series capacitor

formers were considered. It was established from this study that a minimum of 90 ohms was required in parallel with the series capacitor to prevent or damp out resonance with no other load. Figure 9 gives the results of this study which checks with the theoretical calculations discussed previously. For a load of 30,000 kilovolt-amperes at a power factor of 100 per cent, a minimum resistance of 400 ohms is required in parallel with the series capacitor. As the power factor of the load decreases, a higher value of ohms in the resistor is permitted.

Figure 10 shows the range over which the circuit would be subject to subsynchronous frequencies for different loads and different power factors without a resistor in parallel with the series capacitor. It will be noted from this figure that the minimum resonant frequency with no load other than the motor on the line would be about six cycles. This figure also shows the load conditions which do not require a parallel resistor. For example, at a load of 32,000 kilovolt-amperes and 80 per cent power factor, without a resistor, no resonance will occur because this value of load lies outside of the 80 per cent power factor curve.

The results given on Figures 9 and 10 show the ideal or theoretical conditions under which this 4,000-horsepower induction motor will be subject to subsynchronous frequencies. The minimum value of ohms which was established from these studies was 90. The minimum value of ohms specified for the actual installation was 100 which was believed to be a very reasonable figure. As a matter of fact, it was expected that the system will operate satisfactorily with a parallel resistor higher than 100 ohms. A companion paper[1] shows that a resistor of 400 ohms was found to be satisfactory from tests.

Figure 11 shows the amount of 100 per cent power factor load required to prevent self-excitation on the various motors in the steel plant. These curves were calculated neglecting the magnetizing current on the 66- to-12 kv transformers supplying the steel plant. When the magnetizing current for these banks is included, the curve of Figure 11 for 100 per cent power factor and the 4,000 horsepower motor will check with the 100 per cent power factor curve of Figure 10. A load at 100 per cent power factor when converted to ohms is approximately equivalent to shunting the series capacitor with that many ohms in a resistor. Since the 4,000 horsepower motor requires the greatest load to prevent self-excitation, then it dictates the ohms to be provided in parallel with the series capacitor.

Resistor Design

Figure 12 shows the resistor assembly. The top and bottom are open to give adequate ventilation. The opening, however, is covered with screens to exclude rodents, birds, and any other foreign objects.

The resistor assembly for each phase consists of four 400-ohm resistors designed for continuous operation across 7,200 volts. The connections are arranged so that one 400-ohm resistor may be operated alone or two, three, or all four may be operated in parallel. Thus, 400, 200, 133, or 100 ohms may be obtained by proper connections.

Each 400-ohm resistor consists of 72 edge-wound nickel-chrome steel-resistor units. Each unit is wound around a refractory insulator which is reinforced by a stainless steel supporting bar. The units are mounted from each end on zircon (high temperature) porcelains, between two angles, with a 7,500-volt insulator on both ends of each angle.

The resistor units for each phase are assembled in a housing 20 feet long, 7½ feet high, and 38 inches wide. The construction is such that excellent radiating characteristics are secured, thus eliminating localized heating. (The coefficient of resistance of the nickel-chrome steel resistor is 0.000295 ohm per degree centigrade.)

Conclusion

The equipment has been placed in service and staged tests have been made to determine its effectiveness and the value of resistance required. The results of these tests and a description of the substation are given in companion papers.[1,2]

Discussion

Thomas A. E. Belt (Consulting Engineer, Lawrence, Kan.): The two companion papers[1] describing the design and the operation of the 10,000-kva series capacitor installed in the 66,000-volt Phillips-Crucible line of the Duquesne Light Company, contribute materially to the advance of electric power transmission because the data presented show that ferroresonance and subfrequencies during the starting of induction motors can be controlled and that hunting of synchronous motors can be predicted. Furthermore, over various other methods considered for correcting voltage the series capacitor proves to be more adaptable and economical.

The results obtained with this 10,000-kva installation substantiate fully the early experimental work done with the series capacitor. In this pioneering work the basic protective scheme was developed, which consisted then, as it does now, of a spark gap with a by-pass switch connected across the capacitor terminals. A resistance to prevent or to eliminate resonance also was used in this experimental work. In recent tests made on a 33,000-volt transmission system in the Middle West, to determine the feasibility of taking on heavy war loads, variable compensation even to a high degree of over compensation was introduced in the circuits. In spite of predictions and strong criticisms that the system with series capacitors would not work, the tests proved that the assertions of the critics were in error. Series capacitors were installed. Heavy war loads were carried. Better regulation of the line was obtained and the system disturbance caused by fluctuating loads was reduced. All this was accomplished at a fraction of the cost of new transmission facilities.

The following comments are based on the experience which I have had with series capacitors.

Protective Gap and By Pass Switch

Since the spark gap has a low resistance during discharge, the current will be very large and hence the duty imposed on the gap will depend upon the size of the capacitor bank. In certain tests mechanical deformation of the gap during discharge was observed, which failure might have been caused by the sudden expansion of the highly heated air between the gap surfaces. The protective gap used with the 10,000-kva capacitor has one electrode recessed within the other electrode, hence the escape of the high-temperature air during discharge tends to be restricted which may result in the building up of high pressures within the gap chamber. Have the authors any data on the pressures developed between the gap surfaces for discharges from capacitor banks of different sizes?

The time-current characteristics as shown in Figures 5 and 7, of the by-pass switch is relatively slow. For this 10,000-kva installation it is stated that the slow action is of minor importance. In cases where it is desirable to keep a system disturbance to a minimum, it would be better to use a by-pass switch having as short a time characteristic as practical. A magnetic switch without time delay and without external power requirements has been used successfully. Cannot this type of by-pass switch be developed for large installations?

Figure 6 shows that the temperature required to close the switch is 240 degrees and to open it is 200 degrees. Since the ambient temperature may vary over a wide range between summer and winter, will not the time of closing and opening be affected and if so, to what degree?

Fusing of Capacitor Terminal Connections and Blowing of Fuses

In tests made on the 33,000-volt-system mentioned previously, the heavy currents flowing during the gap discharge caused some of the terminal leads inside of the capacitor cases to fuse. Have the authors experienced such trouble? Has any precaution been taken in this 10,000-kva assembly to prevent fusing of the terminal leads? Will a prolonged gap discharge cause blowing of the protective fuses?

Series Capacitors Without Protection

The natural characteristic of capacitor dielectric is such that the short-time dielectric strength is several times its normal rated voltage at 60 cycles. Assume that a capacitor will operate without damage for one second at seven times normal potential; then, if the fault current is not more than seven times normal and does not last longer than one second, the capacitor can be installed without a protective spark gap and by-pass switch. A number of such applications are in operation. Hence, where economy is of major consideration, it may be possible to select a location in the system where the time-potential transient strength of the dielectric will not be exceeded and thus justify a series capacitor installation which otherwise could not be made.

R. E. Marbury and **A. A. Johnson:** In reply to the discussion by Belt we believe that the series capacitor described in the paper is and will continue to be very successful in solving the problems described. We also believe this application indicates that series capacitors can be used in a number of locations where voltage correction and particularly correction of light flicker conditions is needed.

Replying to some of the questions raised in Belt's discussion we would like to say that each part of the assembly has been tested separately and as a complete operating unit.

The momentary pressures within the gap chamber were considered and numerous tests on discharge of large banks of capacitors were made. While we have no specific data on the pressures developed, nevertheless the tests indicated that the gap construction which was used is very adequate to withstand pressures from the currents which may be encountered. The inherent inductance present in the circuit involving the capacitors and the protective gap also limits the maximum peak value of current which can be obtained when a gap breaks down. On capacitor banks larger than the one discussed in the paper it is very likely that resistance will be added in the gap circuit to limit the current and to help dissipate the energy from the capacitors.

Regarding the type of switch used in this application, we recognize that this switch is not applicable where system stability is involved and there is no intention of using it in such an application. Some faster means of clearing a gap flashover is required where stability is involved. Experience has shown the need for time delay to prevent repetitive operation of the switch, particularly on distribution circuits where arcing faults may be encountered. A magnetic or thermal operated switch has serious limitations where stability is involved.

The time of closing the switch on low currents and the time of opening the switch is very much dependent on ambient temperatures. The switch operation, however, is such that it will protect the gap from damage due to prolonged arcing and this is the primary purpose of the switch in this application. The gap protects the capacitor and the switch is necessary to protect the gap.

We have experienced trouble with fuses when using metallic gaps which do not readily ionize. This point is covered in the Owens-Marbury paper given in the reference. The individual fuses used with each capacitor unit in this installation adequately protect the leads inside of the capacitor unit. Only one fuse out of 720 has been blown on this installation and this was believed to be due to a repetitive arcing of the gap caused by motor starting difficulty when the motor starting resistor was temporarily defective. A prolonged operation of a gap of the ionizing type will not damage capacitors due to the absence of oscillating currents through the capacitors.

While we recognize that the capacitor will stand considerable overvoltage for a short time, it is not reasonable or desirable to allow the voltage to reach more than approximately double its nameplate value. If the short circuit currents in a given case are such that the maximum voltage obtained across a series capacitor is within twice its rated value, then we agree that a protective device is not needed. The insulation in other apparatus is never worked nearly as high as it is in capacitors and never near the breakdown value. It is further desirable to limit the voltage during normal use, such as motor starting or short time overloads, to 150 per cent of the continuous rated voltage of the units.

Hystero-Viscosity in Silicone

MICHEL G. MALTI
MEMBER AIEE

A. K. CHATTERJEE
STUDENT AIEE

RESEARCH was undertaken to determine the variation of hystero-viscosity loss with the period of charge or discharge, with the interval between successive charges and discharges as well as with the maximum applied voltage. The material used for this purpose was silicone resin furnished by the General Electric Company and Dow Corning Company. It was found that the hystero-viscosity loss varied as follows:

$$W = aE_m^2(1-\epsilon^{-bt_i})\epsilon^{-c(t_p-T_o)^2} \qquad (1)$$

where W is the energy loss, a, b, c, T_o are positive constants of the material, E_m is the maximum voltage applied to the sample, and t_p, t_i are respectively the period of charge or discharge and the interval between successive charges or discharges.

Preparation of Sample

Silicone, in the form of a resin, was poured over a 4 inch circular disk of aluminum to a uniform thickness of 0.0257 inch and baked at 80 degrees centigrade for 2 hours, at 100° for 1.25 hours, at 120° for 2.5 hours and at 150° for 3 hours.

The solidified sample was then covered with an evaporated metal film. Thus the metal film and the aluminum disk were the two plates of a plane capacitor whose dielectric was silicone. This capacitor was placed in a sealed glass jar containing calcium chloride, to eliminate any humidity, and tested at a room temperature of about 70 degrees Fahrenheit.

Figure 1. Circuit diagram for obtaining the hystero-viscosity loop

Test Procedure

The test circuit is shown in Figure 1 wherein E is a 60-cycle 115-volt source. V, T are variac and transformer respectively. D is a rectifier voltage doubler, using a pair of *705 A* tubes and containing a filter, which gives a steady, ripple-free, continuous voltage. R, S, C, and G are respectively resistances, switches, silicone capacitor and ballastic galvanometer. This circuit was used to obtain several hystero-viscosity loops such as those shown in Figure 2*a*. The procedure was as follows:

The output of the rectifier was adjusted for a certain voltage V_1, the switches S_1 and S_2 were closed so as to impress this voltage on the capacitor for a certain time t_p (hereafter called the period of charge or discharge). During this time the capacitor charge Q_1 was measured by the galvanometer. When t_p had elapsed, the switches S_1 and S_2 were opened for a time t_i (hereafter known as the interval between charges or discharges). At the elapse of t_i the switches S_1 and S_2 were again closed, impressing a voltage $V_2 > V_1$ on the capacitor for a period t_p. During this time the capacitor charge Q_2 was determined. At the end of the charge period the switches S_1 and S_2 were opened for an interval t_i upon the elapse of which a voltage $V_3 > V_2$ was impressed and the condenser charge Q_3 determined. This process was repeated until a maximum voltage V_m was reached and a charge Q_m obtained. After a time t_p had elapsed from the instant of impressing V_m the switches S_1 and S_2 were opened and a time t_i allowed to elapse. Then the voltage was reduced to a value $V_{m-1} < V_m$ and the switches were closed for a time t_p during which the charge retained by the capacitor was determined. The switches were again opened for a time t_i and reclosed for a time t_p at a voltage $V_{m-2} <$

V_{m-1} and the charge retained by the condenser ascertained. This process was repeated until the impressed voltage became zero after which increasingly negative values of voltage were impressed on the condenser for periods t_p at intervals t_i until a voltage $-V_m$ was reached. Thereafter the absolute value of this negative voltage was reduced in varying steps for periods t_p and at intervals t_i until zero voltage was reached and the cycle was completed. The results were then plotted with acquired charge as abscissa against impressed voltage as ordinate as shown in Figure 2a. These curves are known as hystero-viscosity loops. Several loops were obtained under the following varying conditions:

1. Varying maximum voltages applied to the sample. These maximum voltages ranged from 250 to 1,500 volts.

2. Varying intervals between successive charges or discharges. The intervals ranged from 10 seconds to 3 minutes.

3. Varying periods of charge or discharge which ranged from 5 to 90 seconds.

As a result of combining these varying factors some 127 different hystero-viscosity loops were obtained.

The Hystero-Viscosity Loop

A voltage V, impressed on a capacitor, whose dielectric is other than vacuum, causes a charge $Q = CV$ only after the elapse of a certain time other than the normal period of the transient state; this extra time is consumed in some internal adjustments within the dielectric, the actual mechanism of which is not definitely known. This is why the period of charge t_p is taken into consideration in this work. Again after the impressed voltage has been removed and the capacitor allowed to stand on open circuit there is a decrease in the voltage (or charge) across its plates. This decrease is due to causes other than leakage and may be ascribed to internal adjustments within the dielectric, the actual mechanism of which is not definitely known. The longer a capacitor is allowed to remain on open circuit the greater the decrease in charge. This is why the interval t_i between successive charges is a factor in this research.

Now consider the curve, Figure 2b. When the voltage V_1 is impressed on the capacitor for a time t_p, a charge Q_1 accumulates. With the circuit open for an interval t_i, this charge is reduced to a value Q_1'. Thus, if after a time t_i the same voltage V_1 is impressed on the capacitor, the galvanometer would show a charge equal to Q_1-Q_1'. Similarly if after a time t_i a higher voltage V_2 is impressed on the capacitor, resulting in a charge Q_2 then the galvanometer would read a charge equal to Q_2-Q_1'. This charge, when added to Q_1' would give the total charge acquired by the capacitor at a voltage V_2. Thus:

$$Q_2=(Q_2-Q_1')+Q_1'=Q_2 \qquad (2)$$

In this way the charges Q_3, Q_4, Q_m corresponding to voltages V_3, V_4, V_m are also computed. The loops, Figure 2a, do not comprise the subloops shown in Figure 2b. These are omitted for two reasons:

1. We had no means of determining the potentials V_3', V_3', V_m' corresponding to Q_1', Q_2', Q_m'.

2. We had no means of determining the shapes of these subloops and hence the areas enclosed by them. It is our belief however, based on the general shape of the main loops, that the sides of these subloops are virtually

Figure 6. Comparison of experimental and computed results for hystero-viscosity loss as a function of period t_p of charge or discharge

Figure 7. (above). Comparison of experimental and computed results for hystero-viscosity loss as a function of interval t_i between successive charges or discharges

straight lines. Hence the area enclosed by each subloop is extremely small as is the error of omitting the areas. This is particularly true for small intervals t_i. The results of this research are, therefore, good within this error and other errors of observation.

Hystero-Viscosity Loss Curves

It can be shown[1] that the area of the hystero-viscosity loop, Figure 2*a*, represents the energy loss per cycle per unit volume. The areas of the 127 loops were determined and, by the use of proper conversion factors, were expressed as energy loss in microjoules. Three families of curves were then plotted as follows:

1. Energy loss versus period of charge or discharge (Figures 3*a* and 3*b*).
2. Energy loss versus interval between charges or discharges (Figures 4*a* and 4*b*).
3. Energy loss versus maximum applied voltage (Figures 5*a* and 5*b*).

Expressions for Hystero-Viscosity Loss

The curves, Figures 3*a* and 3*b* resemble families of error functions whose equation is:

$$W = W_0 \epsilon^{-c(t_p - T_0)^2} \tag{3}$$

where W is the energy loss, due to hystero-viscosity, t_p is the period of charge or discharge. The constants c, T_0 and W_0 are dimensional constants whose values depend upon the units used and the dielectric tested.

A glance at the curves, Figure 3, shows that T_0 is 40 seconds. This fact leads to the conclusion that silicone suffers its greatest loss when the period of charge or discharge is 40 seconds. Now W_0, equation 3, represents the maximum loss when $t_p = T_0$. It can be obtained directly from the curves, Figure 3, and is obviously a function of the interval t_i of charge and discharge. As to the constant c, this can be determined by substituting various values of t_p and solving equation 3 for c. When the units used are microjoules and seconds, the value of c is found to be 4×10^{-4} per second.[2]

We have stated that W_0 is a function of t_i. To determine this functional relation refer to the curves, Figure 4, and observe that, for any given voltage, the curves are nearly exponential approaching a constant value as t_i increases. Hence for any maximum voltage E_m

$$W_0 = W_1(1 - \epsilon^{-bt_i}) \tag{4}$$

Two unknowns, W_1 and b, are involved in equation 4. But $W_0 \rightarrow W_1$ as $t_i \rightarrow \infty$. Hence W_1 is the asymptote of any of the curves of the voltage families, Figure 4. But by equation 3, $W = W_0$ when $t_p = T_0$. Hence W_1 is the asymptote of that curve in the voltage family, Figure 4, which corresponds to $t_p = 40$ seconds. To determine b, take various intervals t_i, read off W_0, substitute W_1 and evaluate b. When t_i is in seconds and W is in microjoules, $b = 1.8 \times 10^{-2}$ per second.

Now W_1 is a function of the maximum applied voltage E_m. The curves, Figure 5, can be fairly well satisfied by the relation

$$W_1 = aE_m^2 \tag{5}$$

where W_1 is the maximum loss corresponding to a period of 40 seconds and an infinitely large interval t_i. In order to compute the constant a we simply divide W_1 by E_m^2. If E is expressed in volts and W_1 in microjoules then $a = 5.5 \times 10^{-6}$ mho second.

Substitute equations 5 in 4 and the result in 3 and obtain:

$$W = aE_m^2(1 - \epsilon^{-bt_i})\epsilon^{-c(t_p - T_0)^2} \tag{6}$$

Figure 8. Comparison of experimental and computed results for hystero-viscosity loss as a function of maximum applied voltage E_m

which is the expression for the hystero-viscosity loss corresponding to any maximum voltage E_m, any interval t_i between successive charges or discharges and any period t_p of charge or discharge. It is well here to redefine the various symbols occurring in equation 6.

W = hystero-viscosity energy loss in microjoules per cycle per inch cube
a = the voltage loss-constant $a = 5.5 \times 10^{-5}$ mho second
E_m = maximum voltage in volts
b = interval loss-constant $b = 1.8 \times 10^{-12}$ per second
t_i = interval between successive charges or discharges in seconds
c = period loss-constant $c = 5 \times 10^{-4}$ per second^2
T_o = period of maximum loss $T_o = 40$ seconds

Co-ordination of Results

It is interesting to determine how the loss as computed from equations 3, 4, 5, and 6 checks with the experimental results. To do this for all the experimental curves would require more effort and engage more space than is deemed worthwhile. Computations have therefore been made for one curve of each family. The results are given in Figures 6, 7, and 8 where the broken and solid lines correspond to the computed and experimental results respectively. The agreement between computed and experimental results is remarkably close.

Considering the fact that reference 1 contains an extensive bibliography covering the period from 1865 to 1927, the authors have abstained from giving any reference prior to the year 1927.

Relation Between Electrical and Mechanical Parameters of a Permanent-Magnet Movable-Coil Instrument Having a General Circuit

W. N. GOODWIN, JR.
FELLOW AIEE

Synopsis: This is an analysis of the relations between the mechanical parameters and the electrical parameters as measured at the terminals, of a permanent-magnet movable-coil instrument, or other similar electromechanical device, the movable coil of which is free to oscillate, and the circuit of which may consist of any network of resistors which in general may be unknown. It is shown further that by measuring the apparent resistance, inductance and capacitance at the terminals by a special bridge and oscillator and the current per unit deflection, that the values of the undamped period, specific damping coefficient, moment of inertia, and spring stiffness can be computed regardless of the character of the instrument circuit resistor network, or whether it be known or unknown.

IN THE THEORY of electromechanical oscillating systems, such as telephone receivers, vibration galvanometers, mechanical oscillographs, and so forth, it has long been known that the mechanical parameters, when the mechanical system is permitted to oscillate, appear to an external driving source as electrical parameters in the form of impedances.

It has been shown by Wenner[1] and by Kennelly[2] and referred to later by others,[3] that the mechanical parameters can be determined by purely electrical measurements made at the terminals, for direct connected unshunted devices.

R. W. Gilbert, in a companion paper,[4] describes a special bridge and low frequency oscillator which he has developed, by which the apparent electrical parameters of a permanent magnet movable type instrument can be measured much more simply and directly than previously possible. By analogy from available dynamic equations for instruments, he shows also how the electrical parameters as measured on his bridge can be used to compute two mechanical parameters, namely, the undamped period T_o and the specific damping coefficient n. As the latter named term is not generally known, a few words of explanation are necessary. During the period around the year 1908 while making a mathematical analysis of damped motion in instruments and galvanometers, the present author discovered that by using as one parameter, the ratio of the actual damping coefficient to the critical damping coefficient, which he designated n and gave the name specific damping coefficient, and if the time t were given in terms of the undamped period T_o, then the rather complicated equations of motion were reduced to very simple dimensionless forms[5,6] in terms of only two parameters n and T_o. This and other remarkable properties of this ratio n have been in practical use in the Weston laboratories since their discovery. Some of its properties were employed later by Drysdale and Jolley[7] and by Rich.[8]

General Statement of Problem

The object of this analysis is to provide a fundamental proof of the relations between the electrical and mechanical parameters as measured by Gilbert's bridge method, and to show that by making one additional measurement, namely, the value of the current into the binding posts required to produce a known deflection, then the other mechanical parameters, moment of inertia, and spring stiffness also can be determined. This measurement also can be accomplished without opening the case.

In the work of the earlier investigators referred to, a simple series circuit was assumed, and therefore no circuit damping resulted. Using the method here described, however, it will be shown further that all of the parameters referred to can be determined regardless of the character of the circuit in the instrument, provided that it consists of linear noninductive resistors only. That is, the circuit may consist of any kind of network of such resistors and need not be known.

If however, the circuit network is known, then the damping resistance and the fundamental magnetic parameter BAN also can be determined, where B is the magnetic flux density in the air gap, A the effective area of the coil, and N the number of turns on the coil.

Circuit Relations

Let us assume an instrument which has its movable coil connected in some manner to external terminals, and that the character of the connecting network is in general unknown, except that for this analysis it is assumed to consist of linear noninductive resistors. It is further assumed that the effect of the self-inductance of the coil at the low frequencies required in this test, may be neglected.

Now, from a well known network theorem, any resistor network, however complicated, can be reduced to a simple T section.

Let Figure 1 represent the instrument in which the unknown circuit between the binding posts and the movable coil

Paper 48-94, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted October 31, 1947; made available for printing December 23, 1947.

W. N. Goodwin, Jr., formerly vice president in charge of research and engineering, now consulting engineer with Weston Electrical Instrument Corporation, Newark, N. J.

is reduced to the T section, a, b, and r_1 the values of which however, are also unknown, but are, nevertheless, usable in the analysis.

Analysis of General Circuit Having Electromechanical Parameters

When a current which in general is varying flows through the movable coil, a torque is developed by which a corresponding motion is produced in the movable system, as it is free to move. This motion in turn produces a counter electromotive force (emf) $BANd\theta/dt$ which for brevity let us call $Md\theta/dt$, where

Figure 1. Instrument in which the general circuit network is reduced to an equivalent T section

$d\theta/dt$ is the angular velocity of the movable system at any time t.

Figure 2 is a simplified circuit diagram showing the resistances of the parts and the currents in them. Let e be the voltage across the terminals at any time t.

If i_1 is the current at any time through the movable coil, then the voltage across it is

$$v = ri_1 + Md\theta/dt \tag{1}$$

also for the shunt circuit

$$v = bi_2 \tag{2}$$

Then from equations 2 and 1

$$i_2 = \frac{v}{b} = \frac{ri_1 + Md\theta/dt}{b} \tag{3}$$

and the total current entering the binding posts is

$$i = i_1 + i_2 = \frac{(b+r)i_1 + Md\theta/dt}{b} \tag{4}$$

The voltage across the binding posts is then

$$e = ai + v = ai + ri_1 + Md\theta/dt \tag{5}$$

From equation 4

$$i_1 = \frac{bi - Md\theta/dt}{b+r} \tag{6}$$

Then substituting i_1 from equations 6 into 5 we have

$$e = ai + \frac{r(bi - Md\theta/dt)}{b+r} + Md\theta/dt \tag{7}$$

from which

$$\frac{d\theta}{dt} = \frac{e - i[a + rb/(b+r)]}{Mb/(b+r)} \tag{8}$$

It will be observed that the quantity $a + rb/(b+r)$ is the ordinary d-c resistance of the instrument looking in at the binding posts; let us call this r_e. Also $b/(b+r)$ is the shunting ratio, that is the ratio of the movable coil current to the total current, for unvarying currents. Let us call this q for brevity.

Equation 8 then becomes

$$\frac{d\theta}{dt} = \frac{e - r_e i}{qM} \tag{9}$$

Now, when a current i_1 passes through the movable coil, it produces a torque tending to rotate it, $BANi_1$ or Mi_1 for brevity. This torque is opposed by the inertia reaction $Kd^2\theta/dt^2$, by the damping reaction of the damping frame, air and friction, $G_f d\theta/dt$, and by the spring torque $S\theta$ at the angular position θ, where $d^2\theta/dt^2$ is the angular acceleration and $d\theta/dt$ the angular velocity. The effect of circuit damping will enter the equation later through the current produced. Therefore,

$$Mi_1 = K\frac{d^2\theta}{dt^2} + G_f\frac{d\theta}{dt} + S\theta \tag{10}$$

Then

$$i_1 = \frac{K}{M}\frac{d^2\theta}{dt^2} + \frac{G_f}{M}\frac{d\theta}{dt} + \frac{S}{M}\theta \tag{11}$$

In this equation substitute for i_1 its value in terms of i from equation 6, remembering that

$$\frac{b}{b+r} = q \text{ and } \frac{1}{b+r} = \frac{q}{b}$$

and we have

$$iq - \frac{Mq}{b}\frac{d\theta}{dt} = \frac{K}{M}\frac{d^2\theta}{dt^2} + \frac{G_f}{M}\frac{d\theta}{dt} + \frac{S}{M}\theta \tag{12}$$

Now, by differentiating equation 9 we obtain

$$\frac{d^2\theta}{dt^2} = \frac{\dfrac{de}{dt} - r_e\dfrac{di}{dt}}{qM}$$

and by integrating equation 9 we have,

$$\theta = \int\left(\frac{e - r_e i}{qM}\right)dt$$

Substituting for $d^2\theta/dt^2$, $d\theta/dt$ and θ in equation 12 the values just obtained we have,

$$iq - \frac{M}{b}\left(\frac{e - r_e i}{M}\right) = \frac{K}{M}\left(\frac{\dfrac{de}{dt} - r_e\dfrac{di}{dt}}{qM}\right) + \frac{G_f}{M}\left(\frac{e - r_e i}{qM}\right) + \frac{S}{M}\int\left(\frac{e - r_e i}{qM}\right)dt \tag{13}$$

As Gilbert's oscillator produces practically a pure sinusoidal emf, this equation can be integrated for the steady state condition very simply by remembering that in this type of circuit, if the applied emf is sinusoidal, then the resulting current is also sinusoidal having the same frequency as the driving emf but differing in phase from it. A sinusoidal function is the projection on the imaginary axis of a vector of constant absolute value revolving at a constant angular velocity ω. Therefore, letting E and I be the vector values of the emf and current respectively at the binding posts at time $t = 0$, we have

$$e = Ee^{j\omega t}, \text{ and } i = Ie^{j\omega t} \tag{14}$$

Both E and I are complex quantities and as such differ in phase, but both start from their respective phases at $t = 0$, and since they rotate at the same velocity the phase displacement remains constant. For this reason no phase angle appears in the equation 14. Then, differentiating equation 14 we have

$$\frac{de}{dt} = j\omega Ee^{j\omega t}, \text{ and } \frac{di}{dt} = j\omega Ie^{j\omega t} \tag{15}$$

and by integrating equation 14 we have

$$\int e\,dt = \int Ee^{j\omega t}dt = \frac{Ee^{j\omega t}}{j\omega}$$

Figure 2. Diagram of equivalent instrument circuit

and

$$\int i dt = \int I e^{j\omega t} dt = \frac{I e^{j\omega t}}{j\omega} \tag{16}$$

Substituting the values given in equations 15 and 16 in equation 13 and dividing through by $e^{j\omega t}$ which appears as a factor in each quantity, we have,

$$Iq - \frac{E}{b} + \frac{r_o I}{b} = \frac{K}{M^2} \frac{j\omega E}{q} - \frac{K r_o j\omega^2}{M^2 q} + \frac{G_f}{M^2}\left(\frac{E - r_o I}{q}\right) + \frac{SE}{j\omega M^2 q} - \frac{S r_o I}{j\omega M^2 q} \tag{17}$$

Collecting terms in E and I, and combining the reactive terms, we find that the apparent impedance of the instrument looking in from the binding posts is

$$Z = \frac{E}{I} = \frac{q^2 + \frac{r_o q}{b} + \frac{G_f r_o}{M^2} + j\left(\frac{K r_o \omega}{M^2} - \frac{S r_o}{M^2 \omega}\right)}{\frac{q}{b} + \frac{G_f}{M^2} + j\left(\frac{K\omega}{M^2} - \frac{S}{M^2\omega}\right)} \tag{18}$$

In Gilbert's bridge method, which will be referred to later in detail, the resistance of the instrument, measurable on the bridge by direct current, is automatically subtracted from the total impedance. The impedance back of r_o, which is the motional impedance, is then mathematically expressed as $Z_m = Z - r_o$.

Then subtracting r_o from Z in equation 18 and simplifying we have

$$Z_m = Z - r_o = \frac{1}{\frac{1}{q^2 R_d} + j\left(\frac{K\omega}{q^2 M^2} - \frac{S}{q^2 M^2 \omega}\right)} \tag{19}$$

where $R_d = 1/(q/b + G_f/M^2)$ is the combined equivalent damping resistance resulting from circuit, damping frame, and so forth.

This equation gives the apparent electrical impedance produced by the vibratory motion of the movable system as a result of the applied a-c voltage, in terms of the mechanical parameters.

Analysis of Equivalent Electric Circuit

In equation 11 it will be noted that the current is the sum of three components which can be duplicated in a purely electric circuit by the sum of the currents through three parallel circuits, consisting respectively of resistance, capacitance and inductance. One could surmise from analogy which mechanical and electrical constants correspond, but we shall await analysis for the answer.

Figure 3 shows the equivalent electric circuit in which C, L and R are the capacitance, inductance, and resistance respectively, in parallel as indicated by the mechanical equation 11. The resistors a, b and r are the same as given in Figure 2 for the electromechanical problem.

We shall determine the impedance of the circuit looking in at the terminals, for a sinusoidal voltage E applied at the terminals, and then subtract the d-c resistance r_o as was done in the electromechanical problem.

By the usual laws of electric circuits, the impedance looking in at the binding posts can be written directly as

$$Z = a + \frac{\left[\frac{1}{\frac{1}{R} + j\omega C + \frac{1}{j\omega L}} + r\right] b}{b + r + \frac{1}{\frac{1}{R} + j\omega C + \frac{1}{j\omega L}}}$$

Combining the reactive elements, and simplifying, we have

$$Z = \frac{(b+a) + [br + a(b+r)]\left[\frac{1}{R} + j\left(C\omega - \frac{1}{L\omega}\right)\right]}{1 + (b+r)\left[\frac{1}{R} + j\left(C\omega - \frac{1}{L\omega}\right)\right]} \tag{20}$$

But $br + a(b+r) = r_o(b+r)$, since the resistance of the circuit measured at the binding posts with direct current is $r_o = a + br/(b+r)$

Then equation 20 becomes

$$Z = \frac{(b+a) + r_o(b+r)\left[\frac{1}{R} + j\left(C\omega - \frac{1}{L\omega}\right)\right]}{1 + (b+r)\left[\frac{1}{R} + j\left(C\omega - \frac{1}{L\omega}\right)\right]} \tag{21}$$

As was done in the electromechanical problem, subtract from the total impedance Z, the d-c resistance r_o measured at the binding posts and we have after simplifying, the motional impedance

$$Z_m = Z - r_o = \frac{\frac{b^2}{(b+r)^2}}{\frac{1}{b+r} + \frac{1}{R} + j\left(C\omega - \frac{1}{L\omega}\right)} \tag{22}$$

As in the electromechanical problem, let the shunting factor $b/(b+r)$ be designated q for brevity, then

$$Z_m = \frac{q^2}{\frac{q}{b} + \frac{1}{R} + j\left(C\omega - \frac{1}{L\omega}\right)} = \frac{1}{\frac{1}{q^2 R_d} + j\left(\frac{C\omega}{q^2} - \frac{1}{Lq^2\omega}\right)} \tag{23}$$

where

$$R_d = 1/(q/b + 1/R)$$

is the combined equivalent damping resistance resulting from circuit, damping frame, and so forth.

Comparison of Electric and Electromechanical Circuits

Comparing equation 23 for the purely electric circuit with equation 19 for the electromechanical circuit, it is obvious that to have the same impedance under all conditions in both cases the following fundamental relations must exist.

$$\frac{q}{b} + \frac{G_f}{M^2} = \frac{q}{b} + \frac{1}{R}$$

$$\frac{K\omega}{q^2 M^2} = \frac{C\omega}{q^2}$$

Figure 3. Diagram of instrument circuit showing electrical equivalents of the movable coil parameters, resulting from its motion

and

$$\frac{S}{q^2 M^2 \omega} = \frac{1}{Lq^2\omega}$$

From which it follows that,

$$\frac{G_f}{M^2} = \frac{1}{R} \tag{24}$$

$$\frac{K}{M^2} = C \tag{25}$$

$$\frac{S}{M^2} = \frac{1}{L} \tag{26}$$

These equations give the fundamental relations of the mechanical parameters to their electrical equivalents for frame, friction and air damping only for an unshunted instrument. As the shunting ratio, q, in general is not known, R, L, and C, and the corresponding mechanical parameters cannot be measured directly nor computed. However, from equation 23, the apparent damping conductance is

$$\frac{\left(\frac{q}{b} + \frac{1}{R}\right)}{q_2} = \frac{1}{q^2 R_d}$$

which designate for brevity as $1/R_d$. R_d is the motional resistance resulting from all damping including circuit damping, and R_d the corresponding apparent motional resistance. The apparent capacitance is C/q^2 and the apparent inductance Lq^2, which designate for brevity as C_a and L_a respectively. These values can be meas-

ured by Gilbert's method using his bridge and oscillator, but as applied to the general circuit problem.

Then the corresponding instrument parameters from equations 19 and 23 are, respectively,

$$\frac{1}{R_a}=\frac{1}{q^2}\left(\frac{g}{b}+\frac{G_f}{M^2}\right)=\frac{1}{q^2R_d} \tag{27}$$

$$C_a=\frac{K}{M^2q^2} \tag{28}$$

and

$$L_a=\frac{M^2q^2}{S} \tag{29}$$

In equation 23 substitute the values C_a, L_a, and R_a adopted for brevity and we have

$$Z_m=\frac{1}{\frac{1}{R_a}+j\left(C_a\omega-\frac{1}{L_a\omega}\right)} \tag{30}$$

This is the electrical equivalent of the electromechanical problem, the relations of which are given in equations 27, 28, and 29.

Gilbert's Bridge as Applied to the General Problem of a Shunted Instrument

It will now be shown how Gilbert's method is applied to the measurement of the equivalent electrical quantities in equation 30 for the general instrument circuit.

Set up the bridge as shown in Figure 4. Let the bridge ratio be P.

The instrument is connected in arm A_1 in which the upper circuit is the d-c circuit of the instrument, the resistance of which is $r_o=a+br/(b+r)$ and the lower circuit corresponds to the motional conductance resulting from the motion of the movable system produced by the alternating current, in which $R_a=q^2R_d$ is the apparent motional resistance

$$\frac{q^2}{\frac{g}{b}+\frac{Gf}{M^2}}$$

and C_a and L_a the apparent capacitance and inductance, respectively, of the shunted instrument.

Bridge Measurement Procedure

The same method in general will be used as that originally used by Gilbert, which as applied to the general case of the shunted instrument is as follows:

1. With PR_1 short circuited, the resistance Pr_o in bridge arm A_2 is adjusted by using a d-c source until the bridge is balanced. Then the resistance r_o in arm A_2 is equal to the d-c resistance of the instrument circuit

$$r_o=a+\frac{rb}{b+r}$$

in A_1. This resistor Pr_o, is not changed during the test. This performs electrically the mathematical operation of subtracting r_o in equation 22.

2. With the capacitor C_1 disconnected and alternating current used as the source, the frequency and the resistor PR_1 are both adjusted for a bridge balance, and as a result, the measured frequency and movable system are in resonance. Let this frequency be f_o. Then from equation 30 for the angular frequency $\omega_o=2\pi f_o$,

$$C_a\omega_o=\frac{1}{L_a\omega_o} \tag{31}$$

From this the undamped period of the instrument can be computed as

$$T_o=\frac{1}{f_o}=2\pi\sqrt{L_aC_a} \tag{32}$$

Furthermore, from the principle of the bridge, and the fact that at resonance the reactive components cancel, the apparent motional resistance

$$R_a=q^2R_d=R_1 \tag{33}$$

3. With the capacitor C_1 connected, the frequency is increased to a value f_1 or an angular frequency of $\omega_1=2\pi f_1$ at which the reactance of the capacitor,

$$\frac{1}{2\pi f_1C_1}$$

is equal to the resistance R_1, that is

$$\frac{1}{2\pi f_1C_1}=\frac{T_1}{2\pi C_1}=R_1 \tag{34}$$

or

$$T_1=2\pi R_1C \tag{35}$$

where T_1 is the period corresponding to the frequency f_1.

This adjustment Gilbert accomplishes by a running slide rule computation.

It follows then from the principle of the bridge that since the impedance of the capacitor C_1 is equal to the resistance R_1 as a result of the adjustment given in equation 34, then the combined conductance of the L_a and C_a circuits in the instrument is equal to the apparent motional conductance $1/R_a$.

That is, at the frequency f_1,

$$\frac{1}{R_a}=C_a\omega_1-\frac{1}{L_a\omega_1}=2\pi f_1C_a-\frac{1}{2\pi f_1L_a} \tag{36}$$

Computation of Instrument Parameters from Bridge Measurements

By solving equations 31 and 36 as simultaneous equations, and substituting for ω_0 and ω_1 their values in terms of T_0 and T_1, respectively, we obtain the apparent inductance

$$L_a=R_a\left(\frac{T_0^2-T_1^2}{2\pi T_1}\right) \tag{37}$$

and the apparent capacitance

$$C_a=\frac{T_1T_0^2}{2\pi R_a(T_0^2-T_1^2)} \tag{37a}$$

Having thus computed the apparent inductance L_a, the apparent capacitance C_a, and remembering that the apparent damping resistance R_a was measured by the bridge to be R_1, we can compute the specific damping coefficient as follows:

From the theory of damping it is known that the critical damping coefficient is

$$G_o=2\sqrt{KS} \tag{38}$$

From equations 28 and 29, the moment of inertia

$$K=M^2q^2C_a$$

and the spring stiffness

$$S=\frac{M^2q^2}{L_a}$$

Substitute these values in equation 38 and we have

$$G_o=2M^2q^2\sqrt{\frac{C_a}{L_a}}$$

Now, from its definition, as given in the list of symbols, the actual damping coefficient, corresponding to the damping resistance R_d, is

$$G=\frac{M^2}{R_d}=\frac{M^2q^2}{R_a}$$

since the damping coefficient of a damped system is

$$\frac{(BAN)^2}{R_d}$$

where R_d is the effective damping resistance. Then since by definition, the specific damping coefficient n is the ratio of the actual to the critical damping coefficient, we have

$$n=\frac{G}{G_o}=\frac{\frac{M^2q^2}{R_a}}{2M^2q^2\sqrt{\frac{C_a}{L_a}}}=\frac{\sqrt{\frac{L_a}{C_a}}}{2R_a} \tag{39}$$

from which n can be computed from the measured values L_a, C_a, and R_a.

The specific damping coefficient n may have any value from zero to infinity. When n is less than unity, the instrument is underdamped, when $n=1$ critical damping results, and when n exceeds unity the instrument is overdamped. Un-

der the latter condition, n is very difficult to measure directly but is readily determined by the bridge method.

The undamped period from equation 32 is

$$T_0 = 2\pi\sqrt{L_a C_a}$$

It is thus proved that the undamped period T_o and the specific damping coefficient n can be determined in an instrument with a general circuit by the purely bridge method, and that they can be determined by this method whether the instrument is shunted or not, and that the character of the shunting circuit, however complex, need not be known, so long as it consists of linear noninductive resistors only. The damping resistance R_d also can be determined if q is known, by equation 27.

Determination of Other Instrument Parameters Not Measurable by the Bridge Method Alone

As stated previously, only two independent parameters, T_o and n can be measured in general by the bridge method alone. However, by one additional electrical measurement, which also can be accomplished without opening the case, namely, the measurement of the current into the binding posts required to produce a known deflection, then, both the moment of inertia K, and the spring strength S, can be determined regardless of the character of the shunting resistance network.

The magnetic parameter $M = BAN$, and the damping resistance R_d, can be computed if the shunting ratio is known.

Let this measured current be I_o abamperes per radian deflection. Then the current through the movable-coil per radian is

$$i_m = \frac{bI_o}{b+r} = qI_o \tag{40}$$

Now, since the electromagnetic torque produced by L_m is balanced by the spring torque, then

$$BANi_m = S$$

or

$$BANqI_o = MqI_o = S \tag{41}$$

where S is the spring torque per unit angle in dyne centimeter per radian. From equation 41

$$Mq = \frac{S}{I_o} \tag{42}$$

then from equations 28 and 29

$$K = G_a M^2 q^2$$

Figure 4. Basic diagram of bridge circuit showing the electrical equivalents of the motional parameters of the instrument in series with its d-c resistance

and

$$S = \frac{M^2q^2}{L_a}$$

Then substitute the values for Mq given in equation 42 and solving the two equations we obtain

$$K = I_o^2 L_a^2 C_a \tag{43}$$

and

$$S = I_o^2 L_a \tag{44}$$

by which the moment of inertia, and spring strength can be computed from the measured values L_a, C_a by the bridge, and the measurement of the current into the binding posts per unit deflection angle, and the results are independent of the shunting ratio.

Determination of magnetic constant $M = BAN$.

From equations 41 and 44

$$Mq = \frac{S}{I_o} = \frac{I^2 L_a}{I_o} = I_o L_a \tag{45}$$

This shows that the magnetic parameter M can not be determined unless the shunting ratio

$$q = \frac{b}{b+r}$$

is known. If the instrument is unshunted, then $q = 1$ and

$$M = IL_a \tag{46}$$

Example

To show the application of the foregoing principles, the mechanical and electromechanical parameters of a permanent magnet movable coil microammeter were determined by direct mechanical and electrical measurement in the usual manner. The apparent electrical parameters were then measured on Gilbert's bridge by an operator to whom the character of the circuit was entirely unknown. The following apparent electrical values as measured on the bridge were reported.

The apparent motional resistance, inductance and capacitance are as follows respectively:

R_a = (103.0 ohms) = 103.0×10^9 abohms
L_a = (80.0 henrys) = 80.0×10^9 abhenrys
C_a = (2,290 microfarads) = $2{,}290 \times 10^{-15}$ abfarads

The current I_o per radian deflection as measured was 6.15×10^{-6} abampere.

From these data the electromechanical parameters were computed by the equations given, as follows:

The specific damping coefficient from equation 39, is

$$n = \frac{\sqrt{\frac{L_a}{C_a}}}{2R_d} = \frac{\sqrt{\frac{80\times10^9}{2290\times10^{-15}}}}{2\times103\times10^9} = 0.907$$

The undamped period, from equation 32, is

$$T_o = 2\pi\sqrt{L_a C_a} = 2\pi\sqrt{80\times2290\times10^{-6}} = 2.69 \text{ seconds}$$

The moment of inertia from equation 43, is

$$K = I_o^2 L_a^2 C_a^2 = (6.15)^2\times10^{-12}\times80^2\times10^{18}\times2290\times10^{-15}$$

or

$$K = 0.554 \text{ gram centimeter}^2$$

The spring torque per unit angle, from equation 44, is

$$S = I_o^2 L_a = (6.15)^2\times10^{-12}\times80\times10^9 = 3.05 \text{ dyne centimeter per radian}$$

In the general circuit, where the character of the circuit is unknown, the electromagnetic parameter $M = BAN$, and the motional resistance R_d cannot be separated from the unknown shunting factor q. The values $Mq = I_o L_a$, and $R_d q^2 = R_a$ may be obtained from equations 45 and 33, respectively.

In the example given here, however, the circuit was known to the present writer but not to the bridge operator. The movable coil circuit resistance was $r = 64.1$ ohms, and this was shunted by a resistor $b = 170$ ohms, therefore $q = b/(b+r) = 0.725$.

From this value the parameters $M = BAN$ and R_d may be computed as follows:

The electromagnetic parameter from equation 45, is

$$M = BAN = \frac{I_o L_a}{q} = \frac{6.15\times10^{-6}\times80\times10^9}{0.725} = 6.78\times10^5$$

or

$M = 6.78\times10^5$ dyne centimeter per abampere

The motional resistance, from equation 33, is

$$R_d = \frac{R_a}{q^2} = \frac{103}{0.526} = 196 \text{ ohms}$$

The following is a list of the values of the same parameters obtained by the usual direct measurement, and for comparison, the results of the bridge method shown below.

	Direct Measurement	By Bridge
Specific damping coefficient n, numeric	0.885	0.907
Undamped period T_n, seconds	2.70	2.69
Moment of inertia K, grams centimeter^2	0.548	0.544
Spring stiffness, dyne centimeter per radian	2.96	3.05
Electromagnetic parameter, $M = BAN$, dyne centimeter per abampere	6.6×10^8	6.78×10^8
Motional resistance $R_d/10^8$, ohms	209	196

List of Symbols Used

A = effective area of the coil, centimeter^2
a = series resistance in instrument network
B = magnetic flux density, gauses
b = shunt resistance in instrument network
C = equivalent capacitance, abfarads
C_a = apparent capacitance as measured on bridge, abfarads
E = emf vector across binding posts at $t = 0$
e = applied vector electromotive force at any time t
ϵ = basis of natural logarithms
G_f = damping coefficient produced by the damping frame, if any, and the air and friction = damping torque per unit angular velocity, dyne centimeter per radian per second
I = a-c current vector into instrument circuit at binding posts at $t = 0$
I_n = current to deflect the movable system, per unit angle, abamperes per radian
i = current vector into binding posts at any time t
$j = \sqrt{-1}$
K = moment of inertia, grams centimeter^2
L = equivalent inductance, abhenrys
L_a = apparent inductance as measured on bridge, abhenrys
$M = BAN$, for brevity
N = number of turns on the movable-coil
n = specific damping coefficient = ratio of actual damping coefficient to that for critical damping
q = shunting ratio $= b/(b+r)$
r = resistance of movable-coil circuit
r_a = measured d-c resistance of instrument
R = equivalent resistance resulting from the motion of the system only; abohms
R_a = total apparent damping resistance, as measured on bridge, abohms
S = spring torque per unit angle; dyne centimeter per radian
T_n = undamped period, seconds
t = time, seconds
θ = angular deviation of the movable system from its position of equilibrium at any time, produced by the sinusoidal forces
ω = angular frequency, radians per second

A Telegraph Signal Analyzer

G. L. ERICKSON
MEMBER AIEE

THE maintenance of accurate and reliable service over modern automatic telegraph circuits has necessitated the development of testing equipment capable of measuring transmission quality and detecting the causes for transmission irregularities. The telegraph signal analyzer described herein is a small, portable test set designed for this purpose and intended for field use on start-stop telegraph systems. It can be employed for straightaway testing with any form of transmitted text, and hence permits observations of distortion on working circuits carrying miscellaneous signals. The signal analyzer has also proved very useful in measuring the transmission capabilities of telegraph circuits and investigating the relative importance of the various components that make up the total distortion. Other applications include measurements to determine the condition of signals delivered by transmitting keyboards or regenerative repeaters and tests to check the operation of receiving printers. Measurements are made conveniently, rapidly, and with a degree of accuracy which is ample for all field purposes.

When compared with other test equipment similar in purpose, the outstanding feature of this telegraph signal analyzer is that it has been made very simple and very compact. The complete set is much smaller and lighter than a printer, and is also very much cheaper. As shown in the photograph of Figure 1, it is contained in a small metal box measuring only 6 by 9 by 8 inches and weighing only 18 pounds. Two cords are provided for making connections to a source of 110-volt a-c power and to the circuit being tested. On the face of the panel there is a jack and a power outlet which permit a printer to be inserted in the same circuit. The panel also carries the analyzer unit, a power switch, and a second switch for starting and stopping the test. During the test period an observation is made of the distortion on every individual signal pulse as it is received. This has the distinct advantage of indicating the effect of occasional peaks, as well as the average distortion, and also makes it easy to identify troubles that occur systematically. The test results are presented in the form of a permanent record on a paper chart which may be analyzed in detail, measured quantitatively, and retained for future reference.

The printers most commonly used on start-stop telegraph circuits are the 65 word per minute teleprinter employing a 7-unit code, and the 60-speed teletypewriter with a 7.4-unit code. The signal analyzer can be used with either of these codes. It will be recalled that the basis of transmission in these systems is a set of seven pulses which is transmitted for each character. A marking signal is used for the stop pulse transmitted during the idle condition. The first pulse of each character consists of a spacing signal, the start pulse, which is followed by five intelligence pulses. Each of the intelligence pulses may be either spacing or marking. The seventh pulse is the marking stop pulse again, which is transmitted until the start of the next character. From the signal diagram shown in Figure 2, it is evident that the only difference between the 7-unit code and the 7.4-unit code is found in the duration of the stop pulse. In the 7-unit code equal-length pulses are used, and each is of 22 milliseconds (.022 seconds) duration. The pulse lengths are exactly the same for the 7.4-unit system except that the stop pulse is somewhat longer and lasts for 31 milliseconds (.031 seconds). Of course the distinction between the two codes exists only if signals are transmitted at top speed by some form of automatic machine. When a keyboard is operated manually the stop pulses are seldom as short as this and they may be very much longer.

Signals are considered as perfect whenever they are timed as shown in the diagram (Figure 2) to the extent that each of the first six pulses is exactly 22 milli-

Figure 2. Telegraph signal codes

Figure 3. Simplified sketch of mechanism

seconds long. The seven points marked *A*, *B*, *C*, *D*, *E*, *F*, and *G* represent the instants at which signal transitions may be made from marking to spacing or vice versa for distortionless operation. The effect of signal distortion is to advance or retard one or more of the transition points so that it no longer occurs in its proper position with respect to transition *A*, the beginning of the start pulse.

To measure the distortion it is necessary to determine the amount that any transition has been shifted, remembering that time intervals must be measured from instant of the start transition. In the signal analyzer this has been done by establishing reference points 22 milliseconds apart beginning with the arrival of the start pulse, and by then recording with respect to these reference points all transitions as they occur. A circular paper chart is rotated through one complete revolution whenever a printer character is received, and each signal transition in the code is caused to make a mark on the paper. The departure of these marks from radial lines printed on the chart at 22-millisecond intervals is a measure of the distortion.

The operating principle of the analyzer mechanism will be explained with the aid of Figure 3. A start-stop shaft is driven through a slip clutch by a 60-cycle synchronous motor geared down to 420 rpm. The chart is a four-inch disk of Teledeltos recording paper fastened to a small hub at the end of this shaft. When the selector magnet is energized by a marking stop pulse, the stop latch is engaged to prevent the shaft from turning. As soon as a spacing start pulse arrives, the magnet releases the latch and the shaft is free to rotate while the code pulses for one character are being received. The stop pulse at the end of the character brings the shaft to rest again after the chart has made one revolution.

Meanwhile a stylus in contact with the surface of the disk has been energized by the signals and has recorded a series of black marks on the paper. Because it is desired to record only the transitions between pulses, the recording voltage does not appear on the stylus as long as the tongue of the selector magnet is on either its spacing or its marking contact. But while the tongue is moving through the gap between contacts, the stylus receives a short impulse which lasts as long as the tongue is not touching either contact. As a result, current flows from the stylus to the Teledeltos paper during each signal transition and causes a small black mark to be recorded on its electrically-sensitive surface. The recording voltage, represented as a battery in the sketch, is supplied by a rectifier contained within the set.

The recording stylus is moved radially across the paper from the center of the disk to its outer edge by means of a mechanism not shown in the illustration. When it reaches the outer edge of the chart, the stylus returns to the center again and then continue to move slowly back and forth in this manner as long as the test is continued. In each trip across the chart, the signal transitions for approximately 190 characters are recorded. Signals may be recorded on one chart for a period of a half hour or longer.

When the signals received by the analyzer are of perfect quality, free from bias or other distortion, the alignment of the marks recorded on the chart will appear as shown in Figure 4. The seven radial lines printed on the chart at *A*, *B*, *C*, *D*, *E*, *F*, and *G* are reference marks 22 milliseconds apart, corresponding to the signal transition points similarly labeled in Figure 2. Undistorted signals cause all of the marks made by the stylus to fall on these lines. With distortion present the transitions will occur earlier or later than their normal times, and will appear on the chart displaced to an extent deter-

Figure 4 (left). Analyzer chart with perfect signals

Figure 5 (right). Biased signals, letter "y"

A—25 per cent spacing bias B—25 per cent marking bias

Figure 6. Bias charts, letter "Y"

mined by the amount of distortion. The dotted lines 1 to 5 represent the centers of the intelligence pulses and are helpful in estimating the amount of distortion loss.

The speed of the start-stop shaft in the analyzer is 420 rpm which means that the chart is rotated through an angle of 55.5 degrees in 22 milliseconds when running freely without clutch slip. In Figure 4 it will be noted that this is the angle subtended by each of the five intelligence pulses on the chart. When the shaft has been stopped and then released again, a small amount of slip occurs in the clutch before the chart is accelerated to its free speed. The inertia of the rotating parts has been minimized by supporting the paper disk only at the center, but nevertheless the angle for the start pulse is necessarily reduced slightly. The clutch is so adjusted that the chart rotates 46.5 degrees during the start pulse. With a start pulse and five intelligence pulses totaling 324 degrees, an angle of 36 degrees remains for the stop pulse. This is sufficient to insure that the shaft is stopped at the end of each complete revolution even though the stop pulse occurs as much as 14.3 milliseconds late, corresponding to a signal distortion of 65 per cent.

In discussing the effects of signal distortion, it will be of interest to consider the case of bias. Bias is a systematic distortion that displaces every signal transition with respect to its position in undistorted signals. All of the mark-to-space transitions are uniformly shifted in one direction and all of the space-to-mark transitions in the opposite direction. With spacing bias, the directions are such as to lengthen the spacing pulses and shorten the marking pulses. With marking bias, the marking pulses are lengthened at the expense of the spacing. In either case, the net effect of bias in a start-stop system shows up only on the space-to-mark transitions and never on the mark-to-space transitions. The reason for this is made evident by Figure 5, which shows the signal code combination for the letter "Y" with either (*A*) spacing or (*B*) marking bias. It will be noted that transitions *C* and *E* are always properly timed with respect to transition *A*, the beginning of the start pulse. This is because *A*, *C*, and *E* are all mark-to-space transitions and consequently they have all been displaced by the bias exactly the same amount. Hence the effective displacement of *C* and *E* is zero. On the other hand the space-to-mark transitions at *B*, *D*, and *F* are uniformly retarded from their proper times of occurrence by spacing bias, and advanced by marking bias.

The appearance of the analyzer charts for the signals just described is shown in Figure 6. The marks recorded at *C* and *E* fall on the reference lines in both charts. Those at *B*, *D*, and *F* are late in (*A*) and early in (*B*). Since the marks fall mid-

Figure 8. Fortuitous distortion

way between the reference lines and the pulse center lines, they indicate a bias loss of about 25 per cent. Note that there is no transition recorded at *G* because the fifth intelligence pulse is marking, the same as the stop pulse, for this particular signal.

Figure 7 shows charts obtained with the same amount of bias when transmitting miscellaneous signals. At each of the reference points, transitions occur in some of the code combinations and are absent from others. Whenever transitions do occur at *B* and *G*, they must always be from spacing to marking and hence they are all shifted by the amount of the bias. At *C*, *D*, *E*, and *F* transitions can occur in either direction between spacing and

A—25 per cent spacing bias B—25 per cent marking bias

Figure 7. Bias charts, miscellaneous signals

Figure 9. Defective

A—Defective stop contact B—Contact overlap

Figure 10. Tests of cam transmitters

marking, and therefore some appear correctly timed while others are displaced by the bias.

Fortuitous distortion causes the signal transitions to be shifted about in a random fashion so that some transitions are advanced and others are retarded in varying degrees. This causes the marks recorded on the chart to be dispersed in the manner shown by Figure 8. Usually the distortion experienced on a telegraph circuit is due to a combination of bias and fortuitous effects. Then the chart resembles one of those in Figure 7, but includes also the erratic characteristics of Figure 8. The two components are easily separated because the dispersal of the marks at *C*, *D*, *E*, and *F* is caused by both effects, while that at *B* and *G* is due to fortuitous distortion alone. When characteristic distortion is also present, it can be detected by comparing the results of measurements using different recurring test signals.

Examples of charts obtained when using the signal analyzer to check the output of transmitting equipment are given in Figures 9, 10, and 11. In general when there is some irregularity in a sending mechanism, whether it be a printer keyboard, tape transmitter or regenerative repeater, the defect will be manifest as a systematic displacement of certain transitions. The analyzer provides a convenient means for determining the cause of the trouble and following the effect of steps taken to correct it.

In a commutator-type transmitter the signal pulses are sent from a segmented distributor by a rotating brush arm. If one segment becomes worn or dirty, the sending brush will fail to make a positive contact and the signal will be mutilated every time a marking pulse is applied to that segment. Figure 9 shows an example in which the erratic behavior of transition *C* indicates that the segment for pulse number 2 is defective.

In a cam-type transmitter the pulses are sent from a set of contacts which are operated in sequence by rotating cams. The signal transitions will be improperly timed if a cam is defective or if a contact spring is out of adjustment. One example of this is illustrated in Figure 10 (*A*) where the displacement of transition *G* shows that the start-stop contact always closes earlier than normal. If the start-stop contact opens incorrectly, it will advance or retard the start transition and cause all subsequent transitions to be out of place by a fixed amount.

When irregularities are present in the cams or contacts that transmit the intelligence pulses, the marks recorded on the chart by miscellaneous signals will usually overlap in the manner shown by Figure 10 (*B*). The double line of marks at *D* indicates that transitions produced by the opening of contact number 2 are shifted in one direction while transitions due to the closing of contact number 3 are shifted in the opposite direction. The marks at *F* consist of one group perfectly aligned and a second group occurring later than normal. Obviously contact number 4 is opening too late or contact number 5 is closing too late. The exact nature of the trouble is readily determined by observing recurring signals, such as the letter "Y" as compared with the letter "R."

If the speed of a transmitter is too fast or too slow, the displacement of transitions will be as shown in Figure 11 (*A*) and (*B*) respectively. When the speed is too fast the transitions occur early and the marks are advanced by an amount which becomes progressively greater around the chart. When the speed is too slow the marks are retarded similarly.

The operation of a receiving printer can be checked with the signal analyzer by comparing the signal quality revealed by a test chart with the printing range actually obtainable. A defective printing mechanism is indicated whenever the printer fails to yield the expected range. A printer in good condition gives a range of about 80 points with perfect signals. The loss of range due to signal distortion is estimated by observing the transition displacement angle on the chart and comparing it with the 55.5-degree angle between reference lines, which represents one pulse or 100 points of range. It has been found possible to predict the loss within five points by visual inspection alone. Greater accuracy can be secured if a protractor or specially graduated scale is used to measure the displacement angle.

Of course, the analyzer mechanism itself must be properly adjusted if a high degree of accuracy in the distortion measurements is required. However, the device is exceptionally rugged and dependable and requires little maintenance attention once the necessary adjustments have been correctly made. Since the analyzer will always reveal its own imperfections, it is only necessary to check its performance from time to time by driving it with a source of perfect signals.

A—Sender too fast B—Sender too slow

Figure 11. Tests of transmitter speed

Only a few of the more common circuit and equipment troubles have been illustrated by the chart records presented in the foregoing discussion. The telegraph signal analyzer can be relied upon to disclose any type of signal impairment experienced on start-stop telegraph circuits. In some cases careful study and analysis may be required to diagnose obscure troubles and determine the cause of transmission irregularities revealed by a test chart. Nevertheless, it has been found that operating personnel quickly learn to recognize troubles of the types that are frequently encountered. By comparing test results with sample charts illustrating typical examples, they are soon able to use the signal analyzer to good advantage. When the analyzer is employed to check circuit operation periodically, incipient troubles can be detected and corrected before printing failure occurs, thus assuring a high standard of transmission quality and continuity.

Discussion

J. D. McLellan (J. H. Bunnell and Company, Brooklyn, N. Y.): Erickson's paper on the Telegraph Signal Analyzer has been read with great interest by myself and other members of J. H. Bunnell and Company. From a practical application standpoint we feel that the telegraph signal analyzer is a great step forward in automatic telegraph servicing.

When your printer goes out of service or does not work correctly, it is necessary to call in a skilled mechanic, who has in the past been much handicapped by not being able to take with him the proper testing equipment to quickly analyze the trouble and prescribe for it. He is in the same position as a mechanic trying to adjust timing, and set-up the ignition and carburation of one of the modern cars without the modern testing equipment to assist him. The telegraph signal analyzer puts into a small package sufficient testing equipment to analyze and definitely locate the trouble with the printer and with other high-speed automatic telegraph equipment.

We feel that the use of the telegraph signal analyzer brings the adjustments necessary to correct minor deficiencies within the reach of the amateur, making it unnecessary to call in an expert printer man for a minor adjustment.

Our first experience with the telegraph signal analyzer was at a Convention of the Association of American Railways in Miami where we were demonstrating automatic telegraph equipment. The distributor transmitter was evidently thrown out of adjustment during the shipping process to Miami. Skilled mechanics were not available at the demonstration, but a telegraph signal analyzer was, which definitely pointed out which segment on the commutator was not in proper adjustment. The correction took only a matter of minutes and the whole display was quickly put under way.

In fact our own test department is very anxious to put them in use, as soon as we can fill the customers' demand for them.

In short, we feel that the telegraph signal analyzer will fill a long felt requirement, that is, the test equipment can be taken to the seat of the trouble obviating the necessity of taking the trouble to the test equipment.

Recent Improvements in Loading Apparatus for Telephone Cables

Synopsis: Through the use of improved materials, manufacturing techniques, and designs, a series of exchange-area loading coils has been provided which is equivalent electrically to the superseded types but requires one-third less copper and has considerably smaller over-all dimensions. Similarly, 3-coil toll cable loading units have been provided with a saving of one-half in both copper and core material, with a small sacrifice in electrical behavior as compared with superseded types. The reduced size of the new coils and units, together with improved assembly arrangements, made possible a 65 per cent saving in the volume and weight of the cases housing them.

MOLYBDENUM permalloy powder has been available for several years and has been employed in large quantities in magnetic cored coils for loading voice-frequency cable circuits in the telephone plant. This core material has been described, together with its various applications, by Legg and Given.[1]

Improvements in materials and techniques that have become available recently have made possible substantial advances in the design of loading coils. A new insulating enamel for copper wire, known as "Formex,"[2] was found to be much superior to earlier wire enamels in its resistance to abrasion and cracking when flexed sharply. Because of these characteristics it was found to be satisfactory for winding toroidal coils without the supplementary textile insulation formerly required over the enamel. This permitted a considerable increase in the utilization of available winding space. As a result of developments in coil winding facilities it became commercially possible to wind toroidal coils to inner diameters as small as 0.35-inch. This marks a distinct improvement over previous technique, where an inner coil diameter of 0.5 inch was required to accommodate the winding machine shuttle.

These improvements were such as to be worthwhile, if coil designs were revised to take advantage of them. They could be utilized to provide coils having either improved characteristics or reduced size and cost, compared with previous types. A program was undertaken to develop new loading coils and suitable cases to house them so as to achieve the greatest size reduction and saving of materials, consistent with maintaining the existing performance standards. This program was carried to completion for the class of coils used in loading paired conductors of exchange area cable. Preliminary work was also carried out along these lines for three-coil units of the type employed for loading quadded toll cable.

Before commercial manufacture of the new toll coils could be started, however, the demands of World War II made it imperative to reduce the consumption of strategic materials. The most critical items employed in loading coil manufacture were nickel, required for the permalloy core material, and copper for the windings. A study was made to determine the most effective way of reducing the nickel and copper requirements with the minimum loss in performance of loaded cable circuits. No substantial economy of materials could be realized however by any reasonable modification of the new exchange area coil types. A one-third reduction in copper requirements had already been effected and even a drastic reduction of core volume would save only a relatively small amount of nickel since each core contains only one ounce. The toll coil cores, however, employed approximately five ounces of nickel each, consequently they offered the greatest opportunity for the saving of nickel. Data indicated that the transmission penalty in toll cable circuits resulting from a 50 per cent reduction of core volume would be appreciable but could be tolerated. Therefore, the new toll coils were designed on this basis, providing a considerable reduction in the total Bell System consumption of nickel.

The design program outlined previously did not involve any change in the permalloy powder core material, but did require consideration of core and coil configurations to find the optimum dimensional relations. Nonlinear distortion, hysteresis loss and susceptibility to superposed d-c magnetization are directly related to the magnetic flux density in the core. It can be shown that the flux density per unit current varies inversely as the square root of the core volume (within 1.5 per cent for core sizes under consideration), for a given core material and value of coil inductance. The size and shape of a toroidal coil may therefore be changed without appreciably affecting the above characteristics if the core volume remains constant. Reduction of the mean core diameter however, permits more efficient use of a given quantity of core material and fewer winding turns are required. Modifications in core area can be made to secure the desired volume.

Through the use of less bulky wire insulation and improved winding facilities it was possible to reduce materially the size of the exchange area coils and yet maintain the electrical characteristics of the previous types. A 50 per cent reduction in volume of the toll coil with only a slight impairment in transmission performance was thus achieved. The reduced coil sizes, together with improved assembly methods in the redesigned cases, made possible substantial reductions in case sizes and weights.

Paper 48-59, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 18, 1946; made available for printing December 4, 1947.

Winding Machine Improvements

Winding machine improvements included in the present project are considerable, from the standpoint of minimum hole size of the winding, which defines the size of shuttle used in applying the wire to the winding. These improvements have been described primarily in patents.[3] Recent papers[4,5] analyze the behavior of the two-ring machine, which has been the standard form of winding machine for many years. The present improvements can be best understood by reference to the winding operation of the 2-ring machine, which is illustrated in Figure 1. To wind a coil, the dove-tailed and latched sections of both winding rings are removed, while placing the magnetic core ring in position for winding. Wire is then applied to the shuttle ring by driving it forward to take wire from the supply spool. The outer end of the wire is then carried through the guide eye mounted on the guide ring, and around the tensioning pulleys and fastened to the core. Both rings are then driven forward through a differential gear to carry the wire around and down through the hole in the core for the desired number of turns.

One of the major problems in the two-ring type of machine is to prevent excessive tension on the wire as it is applied to the core. The design of the earlier 2-ring machines did not incorporate means for relieving the wire stresses which resulted from the pull necessary to cyclicly accelerate the wire-filled shuttle relative to the driven guide ring. Thus, in order to avoid wire breakage, the machines had to be operated at low winding speeds, with considerable trouble being encountered from the loop of excess wire which was formed during a part of each revolution after the wire guide eye had passed the point of maximum distance from the core.

Figure 1 shows how the recent 2-ring machines use springs and sliding pulleys to take up the loop of wire as the wire-guide approaches that part of its path where it enters the hole in the core, and to give wire out again as it approaches the opposite side of its path. This improvement allowed higher operating speeds, since only the pulleys, their supporting sliders and portions of the springs needed cyclic acceleration. Since these elements had been reduced in mass to the maximum extent consistent with serviceability, the possibility of further speed increases or the adoption of smaller wire sizes depended upon the development of new design features involving less mass.

The tempting savings to be obtained from smaller coils, using smaller wire sizes, could not be realized until a better solution to the problem was found. Also,

Figure 4. Comparison of the new (A, A') and superseded (B, B') cores and coils: A and B, toll cable loading coils; A' and B', exchange area loading coils

Figure 5. Partial and complete assemblies of new (lower) and superseded (upper) toll cable loading units

Figure 6. New (right) and superseded (left) exchange area loading coils suitably encased for individual installation in cable splicing chambers

it became obvious that if a greater proportion of the area occupied by the winding rings could be devoted to wire holding capacity, a coil with a given amount of wire volume could be wound with a smaller hole size. When these conditions were added to the space savings obtainable by the use of the new synthetic wire insulations, with their ability to stand more severe bending and abrasion conditions, as compared with previous enamels or combinations with cotton or silk, new methods and radical changes in the winding ring designs were warranted.

The latest single-ring winding machine, Figure 2, with sliding wire-guide was developed to overcome the outlined limitations. The springs and pulleys in the 2-ring designs have been replaced by a light frictionally engaged sliding wire guide which allows the wire to form a loose loop that is controlled by guide or tensioning plates positioned along each side of the wire path. Now the wire must leave the shuttle around one side of the ring instead of on the center line between the rings as is the case with the 2-ring designs. Nevertheless, the turns of the winding are applied in a substantially radial direction on the core by guide plates appropriately located. A somewhat greater tendency exists with this machine for successive turns to cross each other instead of lying side by side in a layer, but the point of crossover is usually on the outer periphery so "turns space" in the hole of the coil is only slightly wasted.

The ultimate practical limit in size reduction of coils is problematical. As coil size is reduced, the saving in cost of materials assumes a diminishing proportion of total cost. The problem becomes one of maintaining economic balance between the value of space savings to the customer, and the manufacturing cost.

The new ring, Figure 2, developed to wind the smaller exchange area loading coils, being similar to the slightly larger one for the toll coils, is here described. This ring has a mean diameter of three inches and a cross-section diameter of 0.25 inch, and will wind coils having a 0.35-inch hole diameter. It is essentially a thin walled, hollow ring, designed to give maximum wire capacity in the hollow center, with adequate rigidity of structure. The outer surface of one side wall serves as the wire-guide-slider track.

The wire-guide which is caused to slide on this circular track by the pull of the wire as needed, is a short piece cut from a formed ring made to the same diameter as the winding ring. This process insures a suitable fit on the sliding surfaces of the ring, and maximum efficiency in the use of the 0.25-inch cross-section diameter. One end of the wire-guide carries a groove through which the wire slides as it approaches the coil core. The other end provides adjustable sliding spring tension on the slider track of the ring.

A portion of the inner periphery of the winding ring is utilized to provide supporting shoulders and driving gear teeth. With the assistance of modern high strength alloy steels and heat treating methods, suitable wall thickness and diameter dimensions were determined to provide sufficient rigidity of the ring structure to permit operation at speeds up to 1,800 revolutions per minute and still to be flexible enough to be sprung open at a single joint for the loading of the core and the unloading of the coil.

The small size of the new winding ring made it impracticable to construct the conventional dove-tailed and latched removable section. However, as noted before, the ring is made flexible so that, with a single joint, it can be twisted enough out of line to enter or leave the coil. The ring joint is designed to be self-keying. It must be capable of opening and closing many times without causing sufficient wear to change appreciably the pitch spacing between the gear teeth adjacent to the joint, or destroying the alignment of the slider track on the side of the ring, since this could reduce the uniformity of slider friction, causing winding irregularities.

Summarizing, the new single-ring machine consumes less than 50 per cent as much winding space as was the case with the former 2-ring machines. The latest model, Figure 3 winds at a speed of 1,500 turns per minute for wire sizes from 26 to 38 gauge and, when operated at 750 turns per minute, it will wind wire several sizes smaller. The ring is driven by a

geared and belted 2-speed motor with electric brake which is arranged to stop the machine automatically for both loading the shuttle and winding the coil when preset turn counts are reached.

Exchange Area Coils

Since exchange area cable circuits are relatively short, small gauge paired conductors are employed, and small coils having relatively high resistances are satisfactory. As noted herein, in redesigning this class of loading coil the objective was to obtain the smallest possible coil that could be produced commercially, consistent with maintaining the grade of performance of the previous coils. This involved such factors as nonlinear distortion and energy losses in the core, winding resistance, minimum inside winding diameter, ability of winding machines to handle various wire gauges and storage capacity of the winding-machine shuttles. Consideration of these and other factors resulted in the core and coil designs illustrated in Figure 4 in comparison with the previous types. As may be seen, the core diameters are reduced and the axial height is increased. Although this maintains core volume identical with the superseded coil, it entails a coil volume only 60 per cent as large, and the more efficient configuration requires fewer winding turns per unit inductance. Due to the smaller number of turns and the space saving provided by the use of "Formex" wire, the wire size was reduced to effect a 1/3 saving in copper, with no increase in resistance over that of the previous coils. Pertinent dimensional data on the old and new types are given in Table I. The coil winding comprises two equal sections, applied on the two halves of the core, to provide the required circuit balance. This coil type includes several codes having different inductances, and together with suitable cases, described in Table I, has been in commercial production since the latter part of 1941.

Toll Cable Coils and Units

The coils employed for loading voice-frequency toll cable circuits are subject to more stringent requirements than are the exchange area types previously discussed. Those requirements pertaining to d-c resistance, core losses, and nonlinear distortion necessitate the use of a larger core, which in the previous designs had five times the volume of that employed in the small exchange area coils. To conserve nickel, the cores for the new toll cable coils were reduced in volume by 50 per cent.

By properly correlating the factors of reduced core volume, use of "Formex" wire of smaller gauges, and winding machines capable of winding such wire to as small as 0.5-inch inside coil diameter instead of the former 0.75-inch minimum, the new coil designs shown in Figure 4 were worked out. The previous toll cable coil and core are also shown for comparison purposes. The improved configuration of the new core is quite apparent. Dimensional data for both old and new types are given in Table I. The new coil requires 50 per cent less winding copper than did the old one yet, due to the use of the improved features, the winding resistance is only 25 per cent greater than that of the old coil. The hysteresis loss in the core is increased approximately 40 per cent by the reduction in volume, but the increase of total loss is proportionally smaller since other loss components are unaffected by the change in volume.

As described by Shaw and Fondiller[6] voice frequency toll cable circuits are generally quadded, and a phantom circuit is derived from the two side circuits of a quad. A practical arrangement for loading these three circuits consists of a 3-coil unit having two side circuit coils and one phantom circuit coil. The coils are wound with interleaved windings to provide a

* U-shaped cross-section instead of cylindrical as in case of superseded unit.

high degree of balance and magnetic coupling. Each line winding of a side circuit coil comprises an inner section on one-half of the core and an outer section on the other half. The phantom coil windings are similarly divided, each of the four line windings comprising an inner section on one quadrant of the core and an outer section on the diametrically opposite quadrant. The two line windings in each side circuit are therefore closely associated as the inner and outer winding sections on opposite quadrants of the core. When the windings are properly interconnected the consequent close coupling and low leakage prevents the introduction of any appreciable inductance into the side circuits by the phantom coil.

For loading each toll cable quad, two side circuit coils and one phantom coil are assembled together as a unit, both electrically and mechanically. Figure 5 illustrates a partial and a complete unit assembly of both the old and new designs. The three coils are stacked on a central wooden dowel between suitably insulated clamping plates. In the old type units the wooden dowel was drilled longitudinally to accommodate a through bolt employed for mounting the units in the cases. A fibre plate attached to the upper clamping plate carried terminals for connections between the coils and to the case wiring. On this terminal plate were also mounted small toroidal coils and bug-

Figure 10. New (right) and superseded (left) cases containing 51 exchange area loading coils

type resistances employed for crosstalk balancing purposes. In order to obtain acceptably low values of crosstalk between the phantom and side circuits of loading units it is essential that the series and shunt impedances of each side circuit winding be closely balanced. It is generally necessary to add small increments of resistance or inductance or both, in series with the deficient winding to achieve the required degree of balance. Iron washers insulated by fibre washers are inserted between coils to reduce crosstalk between them. Residual side-to-side crosstalk coupling in the phantom coil is counteracted by an opposing coupling between the adjacent side circuit coils, adjusted by rotation of the coils with respect to each other on the central dowel.

Both old and new type units were provided with sheet metal containers for electrical shielding and mechanical protection. In the old type this was cylindrical in form while in the new type it has a U-shaped cross-section with the terminal plate mounted on the open side. Due to the small size of the coils in the new unit, the central dowel serves only to locate the coils, and it is pinned between the metal end plates. Tabs extending from one end of the U-shaped casing serve to anchor the unit in place when assembled in the loading unit case. As may be seen in Figure 5, the small crosstalk balancing coils for the new unit are mounted on one end-plate which is depressed sufficiently for this purpose, while the bug-type balancing resistances lie on the terminal plate. The entire unit, of both old and new types is vacuum impregnated with compound to retard moisture absorption during handling and storage, and to increase dielectric strength.

It should be noted that in spite of the 25 per cent increase in loading unit resistances employing the small coils previously described, the effect on the attenuation, at 1,000 cycles per second, of 19-gauge toll cable circuits is an increase ranging only from 1 to 3 per cent, depending upon the weight of loading. This amounts to approximately 0.25 decibel in

a 50-mile repeater section for the loading system now most frequently installed.

Splice Loading Facilities

In certain instances where it is desired to load only a few circuits in new or existing cables or to replace damaged coils, it may be most expedient to incorporate the coils or units in a cable splicing sleeve. The reduced size of the new coils and units provides a valuable gain in this application, since appreciably smaller and lighter lead splice sleeves can be used than was possible with the former coils.

The exchange area coils have been provided with cases which, as illustrated in Figure 6, are essentially the same for both old and new types except for the difference in size. The case consists of a heavy paper box, with connecting leads extending from one side, and is provided with cotton tapes for tying in place in the splice. The entire assembly is thoroughly dried and wax impregnated to exclude moisture during periods of storage and handling. The encased coils as shown may be installed individually or as groups of six coils mounted on a fibre strip.

Toll cable loading units, electrically the same as those previously described but modified mechanically for incorporation in splicing sleeves are shown in Figure 7. The three coils are mounted on a fibre strip, and a sheet of heavy paper is folded around the unit. The entire assembly is placed in a muslin bag and wax impregnated. The space saving of the new unit over its predecessor is apparent.

A related application for the exchange-area type coil is that of loading long subscriber loops and farmer lines, where a rubber covered pair is buried directly in the ground. Figure 8 shows the new and superseded cases for housing coils arranged so that they may be buried when used with the rubber covered wire. The old case comprised a rather large metal container treated with an asphaltic compound to prevent corrosion. The case housing the new small coil comprises a metal ring around the coil which serves as mechanical protection and support for terminal lead connections, moulded into a soft rubber jacket to exclude moisture.

Loading Coil Cases, General

The greatly reduced size and weight of the new loading coils and units led naturally to the consideration of lighter weight materials in the design of smaller cases to house the coils. A study of various types of case structure resulted in the adoption of a cylindrical arrangement for all cases, the diameters and lengths being varied as required. The superseded cases for both exchange area and toll cable loading were rectangular in cross section except for a few of the smallest sizes which were cylindrical. The new coils and units are mounted on lightweight steel panels which are stacked one above another and assembled in the cylindrical case shells. This makes for economy of different parts and flexibility in handling a range of potting complements, since the number of panel assemblies may be varied as re-

quired, using the same diameter of cylindrical tubing cut to appropriate lengths. Consequently only a few different case diameters are required. Except in certain of the smallest size cases, the mounting panels are circular and the conductors extending from the lead covered stub cable (by means of which connection is made to the main cable) pass through central holes in the panels and branch off at appropriate points for connection to the coils mounted on the panels.

Improvements in stub cable construction were also incorporated in the new cases. These consisted of a 100 per cent increase in dielectric strength between core and cable sheath, for greater protection against lightning damage; reduction of lead sheath thickness to decrease weight and increase flexibility; reduction of crosstalk by new types and increased separation of quads; elimination of brass tape shielding between directional groups, with substitution of paper wrapping; and increased range in the lengths of stub cable that can be furnished as a part of a case, to minimize the need for extra splicing in the field. Cases for smaller complements of coils employ cylindrical lead sleeves with light steel internal reinforcing walls, with steel or brass end plates soldered in place, through one of which passes the stub cable. The lead sleeve cases are suitable for aerial use or in underground cable vaults without modification.

Cylindrical steel casings with steel base plates welded in place are employed for the larger size cases. Through the use of thinner material and the reduced size, the weights of the new cases are approximately 65 per cent less than those of the superseded cases housing the same numbers of coils. The steel cases are used, with slight modifications of mounting details and protective finish, for both aerial and underground installation. Those intended for aerial use have a protective paint finish to prevent corrosion, while those for installation in underground vaults are provided with a composite finish consisting of layers of cloth and asphalt. When cases are to be buried directly in the soil, particularly in areas infested with rodents known to damage lead, the case finish also includes iron wire mesh over exposed lead parts, and the stub cable is protected by the addition of jute wrappings and steel armor. Aerial cases are provided with simple brackets for mounting on poles, eliminating the elaborate pole balconies formerly required for all but the smallest cases. Cases for use in cable vaults are provided with slotted base plates on one end and brackets at the other, for installation on the floor, or in any position on the wall.

After completion, all types of cases are vacuum-dried for several hours by alternate applications of dried air and vacuum through the stub cable. No filling compound is used in these cases, in contrast with the practice generally employed in the superseded types. Instead they are filled with dried air at a pressure of approximately nine pounds per square inch before shipment. When received by the customer the pressure is checked to verify the absence of leaks.

It has been possible to simplify greatly the packing arrangements for the new cases. Formerly it was necessary to employ heavy crates mounted on skids, to insure the cases being handled in an upright position. Also, special steel guards, which were returned by the customer after installation, were required to support the stub cables. The new cases and their stub cables, however, are simply secured to wooden platforms in such a way as to avoid damage to the stub cable. This assembly is then placed in a lightweight packing box which may be handled in any position.

Exchange Area Coil Cases

For purposes of assembly in cases, the previous exchange area coils were assembled on wooden dowels in groups of five or thirteen coils, held in place by end plates which also served as mounting brackets. Such a mounting arrangement was impractical with the reduced dimensions of the new coils. Instead they are assembled in groups of five coils in a sheet-metal container as shown in Figure 9 which illustrates the assembly of both the old and new 5-coil units. This constitutes the basic coil unit employed in all the new cases for this type of coil, with the exception of those for the splice loading applications described previously. The coils are maintained in their positions by the walls of the container and an insulating liner. Two edges of this insulator project through a longitudinal slit in the side of the container and provide a mounting for terminals to which the coil windings are connected by short extensions of

Figure 16 (left). New (right) and superseded (left) cases containing 12 and 14 toll cable loading units, respectively

Figure 17. Internal construction of new case for housing 12 toll cable loading units

the winding conductors. A dished metal cover is stapled in place and applies sufficient pressure to prevent coil movement. A central eyelet type of projection drawn from the bottom of the container, plus a small off-center nub serve as locating media for mounting purposes. This assembly is 50 per cent lighter and has 60 per cent less volume than the superseded five-coil assembly.

Lead sleeve cases are employed for complements ranging from 5 to 51 coils. Although former lead sleeve cases contained up to 100 coils and this number could have been increased with the new coils, steel cases proved to be more economical for complements exceeding 51 coils. A typical lead sleeve case of the new design, housing from 35 to 51 coils is shown in Figure 10, together with its predecessor. Figure 11 shows the internal construction of the case and its principle parts. Three of the coil units are mounted on each of the four triangular mounting plates. Although 60 coils can be accommodated, the usual maximum is 51, since this type of case is normally associated with 51-pair cables.

Cases having tubular steel walls with steel-bottom plates welded in place are provided to house coils in complements ranging from 75 to 450 coils. As pointed out, the steel cases for aerial and underground applications differ only in the matters of mounting details and protective finishes. Figure 12 shows old and new type aerial cases housing 200 coils. Figure 13 shows a similar type 100-coil case having suitable finish and mounting details for underground use, mounted on a wooden platform for shipment. The coil mounting panel employed in cases housing up to 200 coils is circular and accommodates five coil-units which are evenly spaced around the outer periphery of the panel. An internal case assembly of the 100 coil size is shown in Figure 14. Cases containing 300 to 450 coils are assembled with panels mounting ten coil-units per panel, arranged in two concentric circles with five coil-units each. The units in the outer circle are staggered with respect to those in the inner circle to provide accessibility to the terminals of the inner group. This arrangement makes for good utilization of space and at the same time provides ample room for the stub cable conductors which are brought down through the central holes in the panels and branched out between the coil units to the appropriate terminals.

Since the new steel cases have the cable run through the center of the cases, a new assembly procedure was necessary. A suitable length of the sheath is removed from the stub cable, to take care of the internal case wiring. The sheath is soldered into a collar which has been previously welded to the case cover plate. The cover and stub cable are inverted and secured in a fixture. Panel supporting rods are attached to the cover plate and the first panel of coils is assembled over the stub cable and supporting rods. Stub cable conductors are then fanned out between the coil units and connected to the proper coil terminals. A second coil panel is then placed in position and stub cable connections made to the coil terminals. This procedure is continued until the required number of coils has been assembled and wired. A bottom plate is then added and the assembly secured by tightening nuts on the ends of the steel supporting rods. Preformed insulators are placed over the exposed coil terminals and secured by a circumferential wrapping of twine. The cylindrical steel case shell with an insulating liner is then assembled and soldered to the cover to form an air-tight seal. The case is vacuum dried and filled with dried air for shipment.

Toll Cable Unit Cases

Lead sleeve type cases are employed for housing the new toll cable loading units in small complements. Two sizes have been standardized, 1 to 3 units and 4 to 6 units. Figure 15 shows the internal construction of the new six-unit case and of the replaced steel case for eight units. The stub cable conductors are run along one side of the assembly. Two quads branch off from the cable run and pass over the end of each unit through a space provided and fan out to the proper terminals.

Steel cases are provided to house from 7 to 48 of the new toll cable units. Although cases were available for potting as many as 80 of the superseded units, the present maximum of 48 units was believed adequate in view of the expanded use of carrier telephone systems on main cable routes. Figure 16 pictures a 12-unit case of the new design in comparison with a 14-unit case of the superseded type, and Figure 17 shows the internal construction. Six units are mounted on a circular steel panel and are locked in place by means of tabs which project from the unit containers through slots in the plate. Full complement sizes may be provided in multiples of six by use of the required number of panels. Less than full complements may be obtained by substituting empty unit containers for unwanted units. The case assembly procedure is like that described for the nonphantom coil cases, the work being done with the case inverted and the panels assembled and wired in sequence. Six steel rods fastened to the cover plate pass through holes in the panels, the entire assembly being secured by means of nuts on threaded ends of the rods. The stub cable conductors pass through the center of the case and branch out at each panel level passing over one end of each unit for connection to the unit terminals. This arrangement provides a compact and rigid structure with short, direct wiring to all units.

Conclusion

Through the utilization of improved materials and manufacturing techniques a series of coils for loading exchange area cables has been provided which exhibits the same electrical characteristics as the superseded type but employs one-third less winding copper and has considerably smaller over-all dimensions. Similarly, 3-coil units for loading toll cable have been made available which are much smaller then their predecessors and provide a 50 per cent reduction in both winding copper and core material requirements. This large reduction in core material was necessary as a war measure to conserve strategic materials. It results in approximately 25 per cent increase of resistance and somewhat increased nonlinear distortion and susceptibility to superposed direct current. Due to the reduced size and weight of the new coils and units, together with improved assembly arrangements, it was possible to reduce the size and weight of the new coil and unit cases by about 65 per cent.

Trolley Coach Distribution System

G. R. McDONALD
ASSOCIATE AIEE

THE CHANGEOVER of many existing street car systems to trolley-coach operation and the installation of new trolley-coach systems have necessitated the development of a quick and easy method for the layout of the d-c distribution circuits. In this paper the system layout is based on the use of a curve which simplifies the calculations, facilitates checking various arrangements, and provides consistent results with minimum effort. At the same time, it takes into account more factors and provides more information than is readily available with other systems in common use.

The number of vehicles operated during the "rush-hour" periods determines the substation capacity, feeder size and arrangement, and circuit breaker settings. It is evident that this equipment must be of such size and capacity that during the "maximum-demand period" or "rush hour" the voltage throughout the system will permit satisfactory coach operation. Further, this equipment must be so arranged that in the event of a failure of any kind, the system will be adequately protected with a minimum amount of disturbance to the system as a whole.

In general the method is based on the use of a trolley-coach maximum current demand or "diversity curve." Rush-hour conditions only are considered and substation capacity, feeder arrangement, feeder copper and other factors are laid out to take care of these peak conditions. On any particular feeder the number of trolley coaches in operation during the rush hour can be readily estimated. The peak demand current of this number of coaches is then obtained from the diversity curve. It is evident that the substation circuit breaker must be set to carry this peak current and must also answer to the requirement of tripping on a short circuit at the end of the feeder concerned. It has been found by numerous tests that this method of procedure gives adequate operating voltage at the coaches and limits the distribution losses over the peak period to 10 per cent or less.

In order to illustrate the method used, a practical example will be worked out followed by a detailed discussion of the various factors taken into consideration by this method and features of d-c distribution systems which might be considered in making an over-all system layout.

Practical Example

In order to illustrate this method of determining feeder sizes and circuit breaker settings, a solution for the typical problem illustrated by Figure 1 will be worked out. This figure shows part of a system, including an outlying substation and a second substation assumed to be located closer to the load center or downtown section of the city. Three trolley coach routes lettered *A*, *B*, and *C* are shown. It will be noted that route *A* is a stub-end or radial route, while both *B* and *C* are internal station to station routes with multiple feeder circuits. On each route small arrows indicate the rush hour locations and direction of travel of the trolley coaches in service.

The feeder sizes for the stub end route *A* which is the simplest, will be calculated first.

Stub End—A

It will be noted that three coaches are in operation on this 10,000-foot stub-end circuit. If allowance is made for off-schedule operation, the number of coaches which might be expected on this circuit would be increased to four and for this number of coaches we find from Table II, page 3:

Expected load swing	1,157 amperes
Circuit breaker setting (stub)	1,325 amperes
Short circuit current (stub)	1,445 amperes
Line resistance (stub)	0.418 ohms

Using this value of line resistance, it is quite simple with the aid of Table III to select cable sizes that will result in the desired circuit resistance. Using Table III, page 4, the following values might be selected:

4,000 feet of 500,000 circular-mils feeder positive and negative plus trolleys at 0.03-ohms per thousand feet	=0.120 ohms
6,000 feet of 4/0 feeder positive and negative plus trolleys at 0.050-ohms per thousand feet	=0.300 ohms
Total	0.42 ohms

The value of resistance obtained is slightly over and desired, but is close enough for practical purposes.

Now the question is, "What has been done?" In brief, feeder lengths and sizes have been selected to supply current to the coaches on this line at a voltage that is within operating limits. The line losses will be somewhat less than 10 per cent. The feeder circuit breaker setting has been co-ordinated with the feeder circuit resistance so that if a short circuit occurs any place on the line, it will be properly cleared by the circuit breaker.

Multiple Feeder B

It will be noted that there is a total of six coaches shown in operation on feeder *B* between the substations. Three coaches would be carried from each substation. However, due to off schedule operation here again it is assumed that the loading on substation 1 or substation 2, feeders will amount to four coaches. From Table II it is determined that the resistance of this multiple line is 0.432 ohms. This means that the resistance of the 18,000 feet of line between these two sub-

Paper 48-63, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted October 30, 1947; made available for printing December 17, 1947.

G. R. McDonald is in the transportation division, General Electric Company, Erie, Pa.

stations should be 0.432 ohms as although a substation circuit breaker only tends to carry half of the load on the feeder, it must clear on a short circuit in the vicinity of the adjacent substation. From Table III, page 4, it will be noted that 750,000 circular-mils feeder, together with the trolleys, has a resistance of 0.022-ohms per 1,000 feet.

18,000 feet of 750,000 circular-mils feeder and negative plus trolleys at 0.022-ohm per thousand feet	=0.396 ohm

The resistance value obtained is somewhat conservative and the feeder between these two substations on circuit *B* could be tapered somewhat toward the middle of the circuit with a consequent saving of copper. However, this is the main circuit between the two substations and serves as a back-up source of power in case one of the substations is out of service and it is not good practice to economize on copper with this type of circuit.

Multiple Feeder B with Sectionalizing Circuit Breaker at the Center

When a sectionalizing circuit breaker (not shown in Figure 1) is used in this *B* circuit, it is located at the center of the route effectively dividing the circuits into two parts. Each substation supplies power for the same four coaches and from Table II we find as before that the line resistance should be 0.432 ohms. In this case, however, the resistance value will apply to the feeder circuits from each substation to the sectionalizing circuit breaker at the center. Considering 9,000 feet of line, the resistance per 1,000 feet is 0.048 ohms and referring to Table III, page 4, the feeder sizes may be determined:

9,000 feet of 250,000 circular-mils feeder positive and negative plus trolleys at 0.047 ohm per thousand feet	=0.423 ohm

This value of resistance compares con-

† Circular mils.

servatively with the desired limit of 0.432 ohms required for each part of this circuit.

The resistance of the total line from substation 1 to substation 2 is 2×0.423 ohms=0.846 ohms. In the case of a short circuit at one end of the line it is necessary that the setting of the sectionalizing circuit breaker be such as to clear on 710 amperes which is the current obtained by dividing 600 volts by 0.846 ohms. A good rule of thumb is to set the sectionalizing circuit breaker at half the setting of the main substation circuit breakers. From this viewpoint the sectionalizing circuit breaker would be set at one half of 1,270 amperes which is the substation circuit breaker setting obtained from Table II. This gives a setting of 635 amperes, which supplies considerable margin below the actual minimum current of 710 amperes.

A review of the calculations for line *B* shows the following:

1. Without a sectionalizing circuit breaker the feeder must be 750,000 circular-mils and the station circuit breakers will be set at 1,270 amperes.
2. With a sectionalizing circuit breaker the feeder will be 250,000 circular-mils and the station circuit breakers will be set at 1,270 amperes.
3. The sectionalizing circuit breaker will be set at 635 amperes.

Multiple Feeder C

This line is similar to line *B*, the difference being in its length and in the number of coaches scheduled. These factors indicate that it is a line of less importance than route *B*.

There are four coaches in operation on this feeder which would amount to a load of two coaches per station. Here again for off-schedule opeartion, the number of coaches is increased to three per station and from Table II the resistance of the circuit for multiple feed is given as 0.503 ohms which amounts to 0.025-ohms per thousand feet between the two stations. From Table III, page 4, we obtain the following:

20,000 feet of 750,000 circular-mils feeder positive and negative plus trolleys at 0.022-ohms per thousand feet	=0.44 ohm

This circuit could be tapered toward the center to make a saving of copper thus:

12,000 feet of 750,000 circular-mils feeders and negative plus trolleys at 0.022-ohms per thousand feet	=0.26 ohm
8,000 feet of 500,000 circular-mils feeders positive and negative plus trolleys at 0.03-ohm per thousand feet	=0.24 ohm
Total	0.504 ohm

This amounts to 6,000 feet of 750,000 circular-mils feeder positive and negative out of each substation with 500,000 circular-mils feeder positive and negative through the center section. As this is not the main connection between the two sta-

20	2,000	2,200		2,400		0.250	

tions, this tapering of the feeder circuit is considered permissible.

Multiple Feeder C with Sectionalizing Circuit Breaker at the Center

In this case, using the same loading of three coaches per station, it will be seen that the resistance of the line from one substation to the center should be 0.503 ohms which would amount to 0.0503 ohms per 1,000 feet giving the following:

10,000 feet of 4/0 feeder positive and negative plus trolleys at 0.05-ohm per thousand feet	= 0.500 ohm

From Table II we find that the station circuit breakers would be set at 1,090 amperes and by applying the above rule of thumb for setting the sectionalizing circuit breaker it is found that this should be 545 amperes.

A review of the calculations for line *C* shows the following:

1. Without a sectionalizing circuit breaker there will be 12,000 feet of 750,000 circuiar-mils feeder and 8000 feet of 500,000 circular-mils feeder positive and negative. The station circuit breakers will be set at 1,090 amperes.

2. Using a sectionalizing circuit breaker, there will be 20,000 feet of 4/0 feeder positive and negative. The station circuit breakers will be set at 1,090 amperes and the sectionalizing circuit breaker will be set at 545 amperes.

Comparative Costs

For routes *B* and *C* discussed before, two possible arrangements of feeder copper have been worked out, namely, sectionalized and unsectionalized. It is now necessary to cost the two alternative methods of installing feeder and arrive at an economical solution.

Route B Without a Sectionalizing Circuit Breaker

36,000 feet×2.320 pounds per foot× $.30 per pound	= $25,100
36,000 feet×$.09 per foot	= 3,240
Total	$28,340

It is assumed that feeder cable has a cost of 30 cents per pound and that the cost of installation and fittings is $.09 per foot regardless of feeder cable size.

Route B With a Sectionalizing Circuit Breaker at the Mid-Point

36,000 feet×0.772 pound per foot× $.30 per pound	= $ 8,340
36,000 feet×$.09 per foot	= 3,240
Sectionalizing circuit breaker installed	750
Total	$12,330

In this case the saving in the expense due to the use of the sectionalizing circuit breaker amounts to $16,010.

Route C Without a Sectionalizing Circuit Breaker

24,000 feet×2.320 pounds per foot× $.30 per pound	= $16,700
16,000 feet×1.540 pounds per foot× $.30 per pound	= 7,380
40,000 feet×$.09 per foot	= 3,600
Total	$27,680

Route C With a Sectionalizing Circuit Breaker at the Mid-Point

40,000 feet×0.6405 pound per foot× $.30 per pound	= $ 7,680
40,000 feet×$.09 per foot	= 3,600
Sectionalizing circuit breaker installed	750
Total	$12,030

Figure 3. Trolley-coach diversity curve

Figure 4 (below). Trolley-coach overhead

It will be noted in this case the saving by the use of the sectionalizing circuit breaker at this point amounts to $15,650.

In the foregoing discussion it was noted that the sectionalizing circuit breaker for line *B* was to be set to trip at 635 amperes and the similar circuit breaker for line *C* at 545 amperes, making a total of 1,180 amperes. If substation 1 were shut down, it would be necessary through these two sectionalizing circuit breakers to carry a total of three coaches for route *A*, three coaches for route *B*, and two coahces for route *C*. From Table II the load swing of eight coaches omitting all margins, is seen to be 1,464 amperes. It would be difficult, therefore, to operate with substation 1 shut down as the demands far exceed the setting of the sectionalizing circuit breakers.

If the two lines were sectionalized it would therefore be necessary to assume 100 per cent reliability for the equipment in substation 1; otherwise a substation failure would put this part of the system out of service. The total copper saving by the use of these sectionalizing switches is $31,660, or slightly more than the actual cost of the electrical equipment for a 300-kw unit, or about equivalent to this unit when the cost of installation, and so forth, is considered.

Feeder copper in place requires very little in the way of maintenance and has in general a very high recovery value if for any reason the feeder circuit is abandoned. On the other hand, substation equipment requires maintenance and the depreciation is very much greater than the depreciation of feeder copper. For these reasons, it is believed that substation equipment should displace or save at least twice its value in feeder copper, in order to represent an economic application. It would not therefore appear advisable to cut down on the feeder copper as above, and install additional conversion capacity in substation 1.

The feeder *B* is the shortest between the two substations and carries the heaviest traffic. With no sectionalizing, the overall resistance of the circuit as determined above is 0.396 ohm and the circuit breakers at each end of the circuit are set for 1,270 amperes. A desirable combination would therefore appear to be feeder *B* without sectionalization and feeder *C* with sectionalization. The sectionalizing circuit breaker for feeder *C* would be set at 545 amperes, making a total circuit breaker setting of 1,815 amperes for the two circuit breakers in these lines. The total load supplied by these two circuit breakers would be three coaches on route *A*, six on route *B*, and two on route *C*. The demand of 11 coaches is 1,555 amperes. The two circuit breakers should, therefore, if the load is divided in proportion to the circuit breaker settings, be able to supply this number of coaches in an emergency.

A check on the loading of the system when set up in this manner with substation 1 not in service and with the peak loading indicated on Figure 6, indicates that feeder *C* practically takes care of its own load. Feeder *B* carries its own load and most of feeder *A* load. The voltage on feeder *A* over the peak with the loading indicated will be bad. However, operation might be continued with some restrictions on rates of acceleration or increase in headways or another solution might be to use still more feeder copper for route *B*. This could be done without upsetting the economics of a single unit substation installation.

A great deal, in all studies of this kind, depends upon local conditions and the opinions of the management as to service to be rendered, and the risks to be taken.

Explanation and Comments on the Foregoing Method of Calculation

System Map and Loading

The first step in making a study of a trolley coach distribution system is to make up a system map showing each of the proposed routes. Information is then necessary on the number of trolley coaches which will be used on each of these routes over the rush hours or at any time of extraordinary loading on these routes. Knowing the schedule speed, it is then possible to spot coaches on the map. One convenient way to do this is to place a coach at the end of each line and then indicate coaches set out along the line in accordance with operating headways. If the time of layover at the end of a line is assumed to be one-half the scheduled headway, it will be seen that coaches can be spotted along the routes operating in alternating directions and spaced by an amount equal to half of the headway between coaches. When indicating the location of coaches on the map, it should be kept in mind that the schedule speed on the outlying ends of the various lines will be considerably higher than the speed obtained in downtown areas.

Substation Location

As the next step, the substations may be located on the map at what appear to be reasonable locations. These might be at the intersection of two or more lines, or at places where a feeder or feeders may be run for short distances in order to pick up more than one line. A few preliminary checks by the method outlined before

for determining feeder sizes should soon indicate whether or not the substation locations and spacings assumed are adequate. In general, for small systems, substations should be placed with respect to maintaining good voltage on the ends of the lines where the coaches are able to use the maximum speeds. Voltage in a downtown area where traffic conditions slow up the coaches, is of relatively less importance. This system will result in several substations scattered around towards the ends of various lines with comparatively long feeds into the downtown areas. With large systems the loading in the downtown areas will normally be of such magnitude as to prohibit the use of heavy feeders from remote substations and will thus dictate the location of substations at these load centers as well as toward the ends of the lines.

There can be no question as to the adequacy of the location shown for substation 1 in Figure 1, which is the outlying substation. It will be noted that this is at the junction of two routes and is a location where the system may be supplied by three feeder circuits leaving this substation.

Arrangement of Feeder Circuits

Having the location of the substations, the arrangement of feeder circuits is usually quite apparent as in Figure 1. Occasionally the circuits may become quite complicated and a number of trials making different feeder arrangements may be necessary. Feeders should, in general, be arranged to provide the maximum possible amount of sectionalization at a substation; that is, where a circuit runs past a substation the circuit should be sectionalized at such a point rather than merely running one circuit out of a substation to tap into the circuit without sectionalizing. As will be shown later, the copper saved by sectionalizing at such points is usually sufficient to offset many times the cost of additional feeder circuit breakers and circuits.

Another point which will influence the arrangement of the feeder circuits is the number of units in a substation. The cost per kilowatt of substation equipment decreases quite rapidly with an increase in the size of the units used. The cheapest installation of the substation equipment would consist of single units at each of the substations of sufficient size to carry all expected loads at that particular point on the system. Such units should, in addition, have spare capacity for helping out adjacent substations, and the copper should be installed so as to permit ready transfer of power and backup between substations. Where multiple unit substations are provided with reserve capacity, less attention need be paid to backing up this substation from the adjacent stations and, in fact, the circuits between substations might be sectionalized, or a system using stub-end or radial feeders only might be used with a very considerable saving in copper.

Diversity Curve

The system used before for obtaining feeder copper sizes depends on the maximum instantaneous power demand of a number of coaches. Data on this instantaneous demand has been plotted in the form of a diversity curve and it is from this curve that the data of Table II have been compiled. This is one of the most essential parts of the method of trolley coach system layout described herewith.

The current demand of a 44-passenger trolley coach plotted against time is illustrated by Figure 2. This shows that the peak demand for traction from one coach might be considered to be on the order of 350 amperes during initial acceleration. It will be noted, however, that the duration of this peak is only some five seconds when the coach is operating on level profile. When a number of

coaches are operating on a circuit the probability of all coaches starting simultaneously becomes progressively less as the number of coaches is increased. This effect is shown by the curve of Figure 3. The total expected ampere demand of various numbers of coaches is shown plotted against the number of coaches in operation.

At the low end of the curve it will be noted that one coach is indicated as taking 450 amperes. This is larger than the current values given by Figure 2 but includes margin for starting the air compressor simultaneous with starting the coach. This was found to occur quite frequently in practice.

At the high end of the curve with a large number of coaches operating, the current demand obviously must approach the average demand of one coach multiplied by the number of coaches in operation. The current values used are based on an average figure of 50-kw per coach, with a 10 per cent allowance for line losses during the rush-hour period under consideration. The curve therefore approaches 91.7 amperes per coach with large numbers of coaches in operation.

Fifty kilowatts per coach may be considered a relatively high value. It should, however, take into consideration difficult operating conditions as experienced during rush hours and also adverse weather conditions.

The curve is plotted in accordance with the empirical formula:

$I = n\,(91.7 + 358.3 \times 0.82^{n-1})$

I = total current and n = the number of coaches

Figure 8. Result of not sectionalizing at a substation

Curve A—Amount of copper required with line sectionalized at substation 2

Curve B—Amount of copper required with line not sectionalized at substation 2

Curve C—Difference between A and B showing amount of copper saved by sectionalizing line at substation 2

It will be noted that the 91.7 corresponds to the average current and is the ultimate value which would be obtained on the curve for a very large number of coaches in operation. The figure 358.3 is obtained by subtracting the average current 91.7 from the maximum demand of one coach which is taken as 450 amperes.

The factor 0.82^{n-1} is arbitrarily chosen to reduce the load swing portion of the current taken by the coaches as the number of coaches is increased.

This formula is included as an aid in case this method of system layout is applied to different vehicles or to systems which have special operating conditions departing from the average. The values used herewith are based on test data obtained on several systems and are representative of average conditions of feeder conductivity, profile, schedule speeds, and other factors.

Feeder Circuit Breaker Settings

A stub-end feeder is one which receives power at one end or one point only. A multiple feeder is one which receives power at two or more points. When dealing with a small number of coaches, care should be taken to select values from Table II for the proper type of operation.

For any feeder circuit, the number of coaches for normal scheduled operation over the peak period may be determined from the map or otherwise. The expected maximum demand of this number of coaches may readily be obtained from the diversity curve of Figure 2. The feeder circuit breaker should then be set with some margin above this expected demand. A short circuit at the end of the line should then give in turn some margin in current over the setting of the circuit breaker. Table II gives a listing of these data for up to 20 coaches. The load swing current of the second column is increased by 10 per cent to arrive at the circuit breaker setting as given in column 3 and by 20 per cent to arrive at the short circuit current of column 4. The over-all resistance from the substation to the end of the feeder in the case of stub end, to the adjacent substation in the case of multiple feed, or to the sectionalizing circuit breaker if used, is determined from the substation bus voltage (taken as 600) and the short circuit current.

Feeder and Trolley Resistances

Table III gives convenient reference tables for determining the resistance of various combinations of trolley and feeder circuits. This tabulation covers trolley circuits alone and trolley circuits for both one-way and two-way operation, supplemented by various sizes of feeder conductors. The values given are total for the circuit and comprise both the positive and negative sides of the circuit. The tabulation is based on 2/0 trolley wire of 80 per cent conductivity. If other sizes of trolley wire or different conductivity is used, other tabulations may be readily prepared.

Feeder Tapering

Table II indicates the limiting value of resistance which should be used for any feeder with a given number of coaches in operation on this feeder circuit. The minimum weight of feeder copper is obtained when this feeder circuit is made up of a uniform cross section from end to end. On the other hand, minimum losses would be obtained if the equivalent cross section of the conductors, trolley and feeder, were varied in proportion to the square root of the current in each part of the line. This would lead to the idea that where small numbers of coaches are in operation on a particular feeder, a uniform cross section of copper should be used from end to end of the feeder as the losses involved will be a comparatively small factor as compared to the investment in feeder copper. On the other hand, where a comparatively large number of coaches are in operation on a particular feeder, the cross section might be varied in proportion to the square root of the current in

Figure 9. Difference in ground potentials with an unsymmetrical arrangement of feeders

order to achieve minimum losses as losses on a heavy feeder might become an important item. This rule would, of course, be varied somewhat by the cost of a feeder installation; that is, if it were possible toward the end of a line to eliminate feeder altogether, this might be advisable and would justify installing somewhat heavier feeder over other parts of the line.

Operating Voltage

As noted before, the power consumption of a trolley coach is taken as 50 kw. If this value is increased by 10 per cent to 55 kw to make allowance for line losses, then the system should be so designed so that the average line drop to the trolley coach should not exceed 10 per cent with the coaches taking 91.7 amperes each. The average line drop is two-thirds of the maximum average drop. In other words, when the coach is at maximum distance from the point of power supply, its average operating voltage drop should not exceed 15 per cent based on 91.7 amperes per coach. The instantaneous drops will, however, greatly exceed the average and should be based on ratio of the maximum expected instantaneous current demand per coach, as determined from the diversity curve, to the average current per coach.

Referring to Figure 4, it will be noted that the maximum instantaneous ampere swing per coach when 20 coaches are operating is 100 amperes. The allowable maximum instantaneous drop during this load swing would then be $600 \times 0.15 \times 100/91.7$ or 98 volts. Similarly, for 10 coaches the maximum instantaneous drop may be determined as being $600 \times 0.15 \times 152.2/91.7$ or 250 volts. These values are shown plotted on Figure 4 against the number of coaches and illustrate the maximum allowable drop which should be permitted.

It will be noted that with a small number of coaches operating, this curve would tend to give a drop of more than 300 volts instantaneously. The minimum operating voltage of the trolley coach is considered to be 300 volts. The curve is therefore terminated at this value and a line drawn through the range of one to three coaches, giving 300 volts as the maximum allowable instantaneous drop.

When a small number of coaches are operating on a stub-end feeder and the instantaneous drop is not to exceed 300 volts, it is necessary to modify the resistance of the feeder circuit as indicated for stub feeders in Table II. In other words, if one coach has a load swing of 450 amperes and the maximum allowable drop with this load swing is 300 volts, then the resistance of the line will be 0.667 ohms as given in the tabulation. This value permits higher short-circuit current than is obtained on a multiple feeder with one coach and will permit correspondingly higher settings of the substation circuit breakers. Table II has been modified in the range of one to four coaches when operating on stub-end feeders in order to adjust the resistance values in this manner.

When the resistance of the feeder circuit is determined by the methods shown herewith, it has always been found that the operating voltage at the coaches is better than the limiting values indicated on Figure 2. It is therefore not unusually necessary to check voltage drops when laying out the feeder copper.

Voltage Check

The foregoing description of the method for obtaining the voltage drop curve of Figure 4 is somewhat involved due to the use of average maximum and maximum instantaneous voltages. If the voltage curve is accepted, a check on the layout of Figure 1 will indicate its application.

Consider feeder A with normal conditions, as shown by Figure 5. Three coaches are shown, one at the end of the line, one at the halfway point, and one at the substation. From Table II the demand of three coaches is noted to be 998 amperes or 333 amperes per coach. Using these currents and the resistances associated with the foregoing locations, the voltage drop at the end coach will be found to be 196.5 volts. From Figure 4 the maximum drop permitted is 300 volts.

Assume more severe conditions for feeder *A* such as four coaches. The maximum demand current will be 1,157 amperes, 289 amperes per coach. Using uniform spacing for the coaches as before the drop is found to be 223.6 volts. From Figure 2 the allowable drop for four coaches is found to be 285 volts.

For the feeder *B* without sectionalizing which normally supplies six coaches, consider the worst possible condition of four coaches supplied from one substation with no help from the other and these coaches located, one at the center, one 6,000 feet from a substation, one 3,000 feet, and the fourth at the substation. Using 289 amperes per coach and the above distances the maximum drop is found to be 114.5 volts. The allowable drop is 285 volts.

Considering the worst possible conditions for feeder *C* with a sectionalizing circuit breaker, one coach may be located at the sectionalizing circuit breaker one-half way between the circuit breaker and a substation, and one at a substation. Under these conditions we find 242-volts drop which is well within the 300-volt limit.

Figure 10. Multiple type of sectionalizing switch

From these voltage drops it is apparent that stiff operating voltage is always obtained with multiple feeders which are not sectionalized. Good voltage from the standpoint of line losses and average voltage is obtained with stub end and sectionalized multiple feeders.

Substation Units

Having completed a feeder study with substation locations assumed as described before, it is an easy matter to arrive at the capacity required in the substation units. By inspection of the map, the number of coaches taking power from a particular substation may be readily determined within fairly close limits. Some allowance should be made for off-schedule operation and any future growth or other factors which might influence the selection of substation units should be considered. The total number of coaches determined in this way multiplied by 50 kw per coach with a 10 per cent allowance for line losses will give the average load for the rush-hour period. The corresponding load swing may be readily determined from Figure 3.

All conversion equipment for transportation service is rated 100 per cent load continuous followed by 150 per cent load for two hours. The equipment may have a one-minute load swing rating of either 200 per cent for one minute or 300 per cent for one minute. The average rush-hour load as determined before should come within the 150 per cent rating of the unit selected. The load swing rating as deter-

Figure 11. Stub-multiple type of sectionalizing switch

mined from Figure 2 should approximate the load swing rating of the conversion unit.

An example of this procedure will be obtained by referring back to Figure 1. From the layout it will be noted that substation 1 over this peak period supplies power to eight coaches. If we assume 50 kw per coach with 10 per cent line loss, then this average demand is 440 kw. This could be carried by 300 kw units having a 150 per cent two hour rating of 450 kw. Also from Figure 2 it will be noted that the momentary load swing given by eight coaches is 1,464 amperes, equivalent of 878 kw. This 300-kw unit would therefore require commutating ability for at least a few seconds to take care of this expected load swing of approximately 300 per cent. If the conversion unit commutation is limited to 200 per cent it would be necessary to consider the next largest size of 500 kw.

No allowance has been made for off-schedule operation and it is noted that the requirements are very close to the rating of a 300-kw unit. In this case it might therefore be well to consider the next largest size of unit which would be 500 kw. Another factor which bears on this choice would be the fact that the cost per kilowatt of a 500-kw unit is very much less than that of a 300-kw unit. For the electrical equipment of the substation only a 2/3 increase in kilowatt capacity may be obtained with approximately 1/3 increase in the cost of the equipment. This is true because the a-c switchgear, the control equipment and the direct-current feeders would be essentially the same for either unit. In addition, the installation cost, building and land would be practically identical.

For small substations such as considered before it is obvious that in the interest of economy single units should be considered. There is not much risk in this if modern rectifying equipment is considered as the availability of this type of substation equipment is over 99 per cent. In addition, arrangements should be made in the feeder layout to provide for emergency operation with one substation out of service. This may very readily be accomplished where direct feeders can be arranged between several substations. Even in Figure 1 where only two substations are involved, a fairly good arrangement for emergency operation with substation 1 shut down has been obtained in the arrangement of the feeders.

General Comments

System Negative

It is customary to sectionalize only the positive side of a trolley coach system. The negative is permanently interconnected. In many cases it is necessary to run feeder cables for some distance out of a substation to reach the route being supplied. In such cases a compromise on the amount of negative feeder may be made. The positive circuits will all have to be separate and of a size to limit the voltage drop. The negatives of several circuits may be combined with a compromise size of cable as the diversity effect of the load will assist in limiting the voltage drop.

Branch Routes

Figure 5 shows a trolley coach route between two substations with a branch route leaving at a point about half way between the two substations. This presents an awkward situation to handle, as it is difficult to clear a short circuit on the branch route without resorting to an extraordinarily large amount of feeder copper.

Referring to Figure 5, it will be noted that there are eight coaches in operation. It is assumed that the substation circuit breaker at each end of the section would be set to carry five coaches. The short circuit current would be 1,530 amperes; the resistance between substations 0.392 amperes. The solution for the line between substations might be made as follows:

12,000 feet of 500,000 circular-mils feeders and trolleys at 0.03 ohms per thousand feet	= 0.360 ohms

Assume a short circuit at the end of the branch line and no circuit breaker in the branch feeder. This short circuit must trip the circuit breakers at both substations in order to clear. The resistance of the circuits from the two substations to the mid-point where the branch leaves is 0.090 ohms. The current necessary to trip the substation circuit breakers would be twice the short circuit current given before, or 3,060 amperes. The resistance of the branch circuit should be 600 divided by 3,060 minus 0.090 or 0.106 ohms, which would amount to 0.021 ohms per thousand feet and would require 1,050,000 circular-mils feeders.

10,000 feet × 2.320 pounds per foot × $.30	= $6,960
10,000 × $.09 per foot labor	= 900
Total	$7,860

If a stub-end reclosing outdoor type of feeder circuit breaker is installed at the junction between the branch line and the main line, the circuit breaker would be set to carry three coaches and the total resistance from the supply point to the end of the branch line should be 0.438 ohms. Deducting 0.09 ohms for the resistance from the substations to the mid-point leaves 0.348 ohms for the branch line, or about 0.069 ohms per thousand feet.

3,000 feet of 4/0 feeder and trolley at 0.05 ohms per thousand feet	= 0.15 ohms
2,000 feet of trolley only at 0.099 ohms per thousand feet	= 0.198 ohms
Total	0.348 ohms

The cost of this feeder arrangement on the branch line is as follows:

6,000 feet × 0.6405 pound per foot × $.30	= $1,155
6,000 feet × $.09 per foot labor	= 540
Sectionalizing circuit breaker	750
Total	$2,445

The saving by use of the outdoor sectionalizing circuit breaker is $5,415.

Route Crossings

A confusing situation is sometimes presented by route crossings at points where it would not be desirable to install a substation. If the various circuits are all joined together at the point of crossing, a short circuit on any one route is difficult to isolate as although the substation circuit breaker directly feeding the short circuit may open, the current fed from remote points would be divided among a number of circuit breakers with the possibility that the trip point of these various circuit breakers would not be reached. This is somewhat the same condition as discussed

before under the subject of Branch Routes, where a short circuit on the branch might be evenly divided between two substation circuit breakers and thus require a very large amount of short-circuit current to insure tripping.

Figure 6 shows a possible solution to this difficulty which involves the use of outdoor sectionalizing switches for connecting the various circuits together. Each of the four circuits shown might be fed from a different remote substation. However, in effect, the situation is exactly the same as that obtained with a two-track railroad, which is also shown in this illustration. If there is a short on any route, current to this short circuit would be fed into the tie bus through three circuit breakers and this total current would be fed out through one circuit breaker to the short circuit. This would lead to the idea of using polarized circuit breakers, but this is hardly necessary as the circuit breaker which should open always carries the sum of the current of the other three circuit breakers.

Besides affording a ready means of sectionalizing the system at this point, the installation of sectionalizing circuit breakers results in making maximum use of the copper of the various circuits insuring minimum losses and minimum voltage drops.

For reclosing the tie circuit breakers, exactly the same scheme as used in the main line railroad sectionalizing station could be followed, that is, the operating potential for each of the circuit breakers could be obtained from its associated feeder. Then, as soon as this feeder is energized at the substation end, voltage would appear at the tie station and the associated circuit breaker would be closed.

One or more of these feeders might be of the stub-end type without changing this method of approach.

Substation Spacing

Figure 7 illustrates an interesting study on the location of two substations along a trolley coach route. Ordinarily it is considered that with distributed loading along a single line, the substation nearest the end of the line should supply a stub end of the system which would be half of the distance between substations. This is so if considered with a uniform copper section throughout the line and considered only from the standpoint of voltage drop. Figure 7 shows two cases which have been studied.

Case 1 shows a section of trolley coach route 24,000 feet long with seven trolley coaches spaced as indicated. This situation was studied from a theoretical standpoint using odd copper sizes and considering uniform section of feeder copper throughout each part of the system. If the complete line were supplied from substation 1, it will be noted that 185,000 pounds of feeder copper would be required. This feeder copper may be reduced by installing a separate substation indicated as substation 2. It is interesting to note that without any sectionalizing in the line between substations as indicated for case 1, to obtain minimum copper the second substation would be spaced at approximately 58 per cent of the distance from substation 1 to the end of the line.

Case 2 illustrates the effect of installing a sectionalizing circuit breaker between the two substations. In this case the sectionalizing circuit breaker may be set to trip at half of the value used for the substation circuit breakers, and the resistance of the line between the two substations may be increased as it is not necessary for the substation circuit breaker to trip on a short circuit any farther away than half of the distance between the two substations. Under these conditions, using exactly the same loading, it is found that the total amount of feeder copper for the system may be very considerably decreased and the most economical location for the second substation is two-thirds of the distance from the first substation to the end of the line.

In Case 2 with a sectionalizing circuit breaker between the substations and the copper section reduced to a minimum, it is obvious that the outlying substation, substation 2, must have complete reliability as it would not be possible to handle the traffic indicated from substation 1 only. Line drops would be excessive and the low setting of the sectionalizing circuit breaker would also make operation without substation 2 prohibitive. This would probably indicate the installation of two units in substation 2, either of which would be capable of supplying all of the load demand. If a greater amount of copper were used between the substations, then the two substations would provide mutual support and the sectionalizing circuit breaker half way between the two substations would not be required. In this case, the additional copper could very readily be offset by reduced investment in substation capacity.

Result of Not Sectionalizing at Substations

In many cases it is common practice not to sectionalize the distribution circuits at substations particularly where the substation is near the end of the particular line. Figure 8 illustrates that this practice may be extravagant of copper if the circuits are laid out to provide isolation of short circuits. Curve A of this figure is the same as Curve ACB of Figure 7, and gives the total weight of copper required as the location of substation 2 is varied over the length of the line. The line in this case is sectionalized at substation 2. Curve B shows the weight of copper required if the line is not sectionalized at station 2. Curve C shows the difference between curves A and B or the saving in copper obtained by sectionalizing.

Feeder Location with Rectifier Power Supply

It is customary to carry the positive and negative feeders of a trolley coach system on one side of a street, as this can be done by using one cross arm. The idea of carrying the positive and negative feeders on opposite sides of a street has been discussed. This would be more expensive and in addition if the power is supplied by rectifiers, might be somewhat objectionable. The d-c output of a rectifier contains harmonics which may cause telephone interference if there is magnetic coupling between the d-c power and telephone circuits. Short distance between positive and negative circuits reduces the chances of having this type of trouble.

Grounding Practice

Many different practices are followed in grounding trolley coach distribution systems. Some systems operate without grounds of any kind, others operate with the negative grounded at each substation.

Figure 12. Typical substation

A compromise between these two used by some companies is to have the negative permanently grounded at the base load or most important substation. The negative at other substations is then grounded only when these substations are in operation and are connected to the line.

With the negative grounded at the station only, it is customary to use lightning arresters at intervals along the distribution circuits connected from both the positive and negative circuits to ground.

With the negative permanently grounded at each substation, it is possible to have ground current between substations when a substation, between the load and its source of power, is not in service. The compromise scheme of a permanent ground at one substation and grounds at other substations only when they are in service, would appear to have several advantages. Ground current between substations should be eliminated. Lightning protection for the substation equipment and safety of operating personnel should be the equivalent of that obtained at substations having the negative permanently grounded.

Unequal Ground Potentials

Where grounds are used at substations, care should be exercised to prevent differences of potential between the grounding points. One cause of such differences might be an unsymmetrical arrangement of positive and negative circuits as illustrated in Figure 9. The constants chosen for this illustration are such as to exaggerate the effect. The same thing is, however, possible with distributed loading. Such an unsymmetrical arrangement might be introduced when a changeover is made from street car to trolley coach operation.

Bare Conductor Heating

It is sometimes necessary to check the current carrying capacity of bare conductors. These data shown in Table I, are not readily available, and are therefore included for easy reference.

As noted before, there are many different approaches to this problem of trolley coach system layout and any method used necessarily involves arbitrary assumptions and approximations.

It is believed that the system of layout described herewith has considerable advantage as it provides a quick, easy approach which takes care of

1. Proper operating voltage.
2. Feeder circuit breaker settings.
3. Isolation of short circuits.
4. Necessitates close attention to the arrangement of feeder circuits.
5. Facilitates quick checking of over-all costs with various substation locations and arrangements.
6. The cost of a layout obtained by this method will not be more than that of a good layout obtained by other methods. Actually the cost will probably be less due to the ease of checking various arrangements.

This method of system layout in its present form has been in use for somewhat over three years and even before this time was used in principle from time to time as the occasion demanded. It is believed that sufficient experience has been obtained to permit recommending the use of this procedure on all trolley coach power supply distribution problems.

Discussion

S. M. Dougherty (Westinghouse Electric Corporation, East Pittsburgh, Pa.): McDonald's paper on trolley coach distribution system contains a very interesting approach to the problem of laying out the feeders and substations for a trolley coach system. Considerable experience and thought must have entered into the preparation of the various tables and curves which are used to determine the system components. It will be found, however, that the data presented do not consider at least one feature which would permit further economies in feeder copper. This is the use of short circuit detector equipment instead of straight overload protection.

When short circuit detector equipment is used the circuit breaker is tripped only when a fault occurs on the particular feeder or trolley. On the other hand, legitimate loads do not trip the circuit breaker. This is true even though the current which results from a fault at the end of a long feeder may be considerably under that required to accelerate coach loads concentrated closer to the substation. Because of this ability to discriminate between legitimate load swings and current rate of rise resulting from a fault anywhere on the feeder, the short-circuit detector system provides the greatest continuity of service as well as maximum economy in the amount of feeder copper required.

As applied to an ordinary feeder, the short circuit detector scheme is made up of three items; an impulse coil which supplies the tripping intelligence, a polarized instantaneous detector relay which functions when the fault is near the substation and a short circuit selector relay which operates for faults beyond the range of the instantaneous relay.

In effect, the impulse coil is similar in construction to a through-type current transformer except that it is specially designed so that it will not be saturated either by normal direct current load current or by current resulting from a short circuit in the feeder. As long as the feeder current remains constant, there is no voltage induced in the secondary winding of the impulse coil. When the feeder load changes, for example due to a coach starting, the resulting flux change in the impulse coil will cause a current to flow through the short circuit detector and selector relays which are connected to the impulse coil secondary. However, the rate of change or the magnitude of this load current will not circulate enough secondary current to operate either relay. When a fault occurs near the substation, the short circuit current will build up to its maximum value in a comparatively short time. This rapid change in current will produce a high current peak of short duration in the impulse coil secondary. This current flowing through the high-speed short-circuit detector relay will be sufficient to cause it to operate and trip the feeder circuit breaker. If the fault is at or near the end of this feeder, there will be a greater ratio of inductance to resistance in the circuit. Because of this, the rate of increase and the final value of this fault current will not be as great. As a result, the impulse coil secondary current will be of longer duration but the peak value will be less than that resulting from a short circuit near the substation. This peak will not reach a high enough value to operate the short circuit detector relay but the duration will be long enough to cause the selector relay to close its contact and trip the circuit breaker. It should be noted that the short circuit selector relay is set to operate at a value considerably under the detector relay setting, but its inherent time delay will prevent tripping on faults near the substation or on the impulse peaks which result when one or more coaches are accelerating. This method of short circuit detection has been in use for a number of years on various types of transportation systems and has given excellent service.

Twenty-Five Years of Copper–Copper Oxide Rectifiers

L. O. GRONDAHL
FELLOW AIEE

WHEN it was decided to do the copper-oxide rectifier the honor of celebrating the 25th anniversary of its origin with a session on the subject, the choice of the date obviously had to be arbitrary. The first discovery of the rectifying phenomenon that exists between cuprous oxide and the copper on which it is formed was made in November, 1920, 27 years ago. The first practical use of the rectifier was made in 1924, 23 years ago. The average of the two figures is 25 years, so the date seems appropriate. The writer has been assigned the privilege of reviewing the history.

Discovery and Early Development

The discovery of the rectifying characteristic of a copper-cuprous oxide junction was a by-product of another investigation, which at that time was of interest in railway signaling. There existed among railway signal engineers a conviction that relays with moving parts could be improved upon by substituting something that would function in the same way without the movement of parts and without contacts that had to be closed and opened mechanically. The obvious procedure was to study all the different physical devices which had impedances that could be changed at will, with the hope that by the use of such devices and by changing impedances from high to low and vice-versa as required, it would be possible to provide the equivalent of opening or closing an electric circuit by means of contacts. In this effort a study was made of the use of vacuum tubes, gas-filled tubes, light sensitive cells, heat sensitive cells, and variable reactors in circuits that could be substituted for the standard signaling circuits using electromechanical relays. It was found possible on paper to set up such equivalent circuits and many of them were drawn in detail.

For reasons that need not be discussed here, light sensitive cells seemed at one time likely to be the most practical, at least if they could be made with a very low illuminated impedance. The two light sensitive materials that seemed most likely to be useful were selenium and cuprous oxide. Selenium seemed less promising because its behavior up to that time had been found in the laboratory to be very erratic, and to depend on many conditions of heat treatment. Cuprous oxide on the other hand had been found to be more consistent in its behavior.

It was realized that in order to get a cell of sufficiently low impedance to provide a circuit to energize lamps or other equipment, it would be necessary to use a path in the cuprous oxide which is short and of great cross section, since cuprous oxide is a semiconductor of high resistance compared to metals. This consideration led to the conclusion that it would be necessary to conduct the useful current across a thin sheet of cuprous oxide. Cuprous oxide is a brittle material, and would be difficult to produce and to use in thin sheets. This led to the very fortunate expedient of producing the cuprous oxide on a sheet of copper by oxidation and to stop the oxidation when there was still enough copper left to serve as a support for the sheet of cuprous oxide, and at the same time to serve as a contact to one side of the semiconductor.

The first unit was made by placing strips of copper in a nichrome furnace operated at temperatures between 900 and 1,000 degrees centigrade and oxidizing for approximately an hour. Since it was feared that rapid cooling would crack the oxide, the cooling after oxidation was made slowly. During the cooling a certain amount of cupric oxide formed on the surface of the cuprous oxide. The unit was prepared for the photoelectric experiment by breaking off the cuprous oxide at one end of the strip to make it possible to make connections with the copper. The cupric oxide on the surface was ground off on an emery wheel and a contact was made to the free surface of the oxide by laying a piece of lead against it and pressing the surfaces together by means of a clamp. See Figures 1 and 2.

The unit was then put in an ordinary Wheatstone bridge circuit to determine its resistance and to determine the effect of illumination on that resistance, with the hope that illumination would drop its normally high resistance to such a value that reasonable amounts of current could be passed through it without the use of excessive voltages. In the Wheatstone bridge the unit had a resistance of 400 ohms, and the illumination of the unit had no observable effect on its resistance. This seemed strange so the experiment

Manuscript submitted November 20, 1947; made available for printing December 12, 1947.

L. O. GRONDAHL is consultant in research, Westinghouse Air Brake Company and Union Switch and Signal Company, Swissvale, Pa.

It is not possible here to list all of those who have contributed to the development of the copper oxide rectifier. Very substantial contributions have been made by Dr. P. H. Geiger and Dr. P. H. Dowling.

Figure 2. First rectifier assembly

Figure 3 (right). Resistance-voltage characteristic of first rectifier measured in new assembly nine years after oxidation

was repeated under varying conditions for several days. During this experimentation it was found that sometimes the resistance as shown by the bridge was 400 ohms, and at other times it was 1,200 ohms. The existence of these two definite values of resistance was a puzzle until it was discovered that the resistance depended upon the polarity of the battery used to energize the Wheatstone bridge or similarly on the way in which the copper oxide unit was connected into the Wheatstone bridge. This immediately looked like a rectifier, but it was not realized fully at first that even such a ratio might be useful in some rectifier applications, Figure 3. The unit was laid aside for a while on account of the urgency of the original problem, namely the finding of a suitable relay without moving parts.

Some months later there arose the need of a rectifier to charge a small *B* battery. There was also needed a rectifier for use on a locomotive in train control apparatus to operate a d-c relay from an a-c source. In such applications the small rectifiers that were available at that time were not very suitable. There were, for instance, the aluminum wet rectifier, rectifiers using vibrating contacts, and other similar cumbersome equipment difficult to maintain, and difficult to use under any condition and especially so under the conditions existing on a locomotive. It seemed likely that the copper–cuprous oxide combination that had been observed some time before might be developed into a useful rectifier for these purposes, and the attempt was made at once. By the fall of 1921 the rectifier began to show promise. At that time it had been concluded that the practical way to assemble such units and to put many elements in series or in parallel was to make the units in the form of washers and to assemble them on bolts with the necessary connectors and insulators.

In these early experiments there was a bewildering mass of details that had an effect on the result, and on the usefulness of the device. Nothing was known about suitable voltages, current densities, type of copper to use, heat treatments, methods of making contact to the free surface, and many other details too numerous to list now. In spite of this the unit became useful partly because the competitive units available at that time were very poor. Efficiencies of about 20 per cent and very short life was the best that could be had in the existing equipments. By 1924 the first practical installation was made. At that time the rectifier was used in a train control equipment on the Delaware, Lackawanna and Western Railroad to operate a d-c relay from an a-c supply. The rectifier is still in use in that same application.

The subsequent growth of its usefulness was rapid and by the fall of 1926 it had gone into production at the Westinghouse Electric Corporation's plant for use as an *A* battery charger, since this was before the advent of the vacuum tube with an indirectly heated cathode. During the latter part of 1926 this production rose to 6,000 *A* battery chargers a day. In 1926 the development of the rectifier was announced at a meeting of the American Physical Society.[1] A proposed theory for the copper oxide rectifier was published in that same year.[2]

Since that time the cuprous oxide rectifier has enjoyed a steady growth in three phases:

1. Development of theory.
2. Improvement in quality of the rectifier and in variety of characteristics and of applications.
3. Steady increase in production in all industrial parts of the world.

Theory

We shall not have time here to go into a full discussion of all the theoretical suggestions that have been made to explain the performance of a copper oxide rectifier. These suggestions range from a geometric arrangement of parts through thermoelectricity, electrolytic action, work functions, the assumption of the existence of an insulating layer, and even to the assumption of a physical separation between the oxide and the mother copper to a combination of many of these, with the assumption of the presence of an electron atmosphere in the cuprous oxide.

The physical facts that have to be explained may be listed as follows:

1. The asymmetric impedance is found to be concentrated at the junction between the mother copper and the cuprous oxide.
2. When voltages applied approach zero, the resistances in opposite directions approach equality.
3. It follows at once that the asymmetry in resistance depends on the voltage applied, and is not inherent in the unit in its normal stabilized condition.
4. In the low resistance direction and at low voltages the impedance decreases approximately exponentially as the voltage increases. At higher voltages the low resistance becomes nearly constant.
5. In the high resistance direction the impedance increases with increasing voltages up to a very high value at approximately $1^1/_2$ volts beyond which it decreases with increasing voltage at a rate that is nearly linear.
6. It is found that when the areas are substantially equal the rectification always takes place at the junction even when the contact on the free surface is made with

Figure 4. Resistance-voltage characteristics and resistance ratio of air cooled disk (area 10 square centimeters)

copper, so that the cuprous oxide lies between two copper contacts.

7. The last observation in common with many others indicates that the type of contact or junction between the cuprous oxide and the mother copper is quite different from ordinary solid contacts.

8. There is a considerable electrostatic capacity at the junction between the copper and the cuprous oxide.

9. Except for this capacity the impedance in both directions is a pure resistance.

10. The asymmetric response to applied voltages is instantaneous.

11. Illumination of the junction produces a photoelectromotive force.

A theory that was proposed in 1926 took these facts into consideration, and while it is very crude in view of more recent developments in the theory of semiconductors it, nevertheless, contains the fundamental element of an electron atmosphere in the cuprous oxide which is also in principle a part of the present more sophisticated theory.[4] A discussion of these theories will be included in the oral presentation.

Practical Development

The copper oxide rectifier has enjoyed one condition that was ideal for the development of a new tool. At the beginning competitive devices were so unsatisfactory that even the crudest type of copper oxide rectifier found useful applications. It was not necessary, therefore, for the copper oxide rectifier to come into the market at the beginning in its most highly developed form. As the development proceeded, new applications became possible so that there was at all times in the commercial situation encouragement for further development. The novelty of the device was well illustrated by the attitude of the United States Patent Office. It became necessary in the early prosecution of the patent applications to provide evidence in the form of affidavits executed by competent engineers, testifying to the performance of the device.

The making of the first units has already been described. In the attempt to develop the process to produce better rectifiers, many conditions, each one of

Figure 5. Voltage-resistance characteristics of water quenched washer

Figure 6. D-c volt ampere characteristics

which was capable of almost an infinite number of variations, became important. An enumeration of some of these details of production may be worth while and is given at this time.

1. *Temperature of Oxidation.* The first units were oxidized at a little over 900 degrees centigrade. It was soon found that the temperature of oxidation was important and that usually higher temperatures produced better results so that the temperature of oxidation was increased to 1,000 degrees centigrade, and later to the highest temperature that could be used without deforming the blanks by softening of the copper. Since then it has been found that some coppers give the best results at the highest possible temperature while other coppers give better results at somewhat lower temperatures of oxidation.

2. *Duration of Oxidation.* Obviously from a practical standpoint this should be as short as possible, and it was found practical to reduce it from the one hour that was used in the first units to 13 minutes and sometimes considerably less.

3. *Rate of Cooling.* This is very important in the control of the characteristics of the rectifier and will be discussed in greater detail.

4. *Purity of Copper.* Coppers from all available sources of supply were tried and while all were considered pure copper from a commercial standpoint, it was found that there were great differences among them when used in the production of copper oxide rectifiers. These differences were eventually found to be dependent on the presence of very small amounts of impurity in the copper.

5. *Surface Conditions.* In the early stages of the development, much emphasis was laid on the conditions of cleanness of the surface, and of its degree of roughness. A clean surface is still considered absolutely essential. The mechanical condition of the surface as well as the hardness of the copper are not now considered of great importance.

6. *Thickness of Copper.* The first units were made with copper that was 1/8 inch thick. It was found that when the oxidation takes place on one side only, the copper buckles due to unequal thermal contraction of the copper and the cuprous oxide. At first it was thought that this was important because it was believed that the cuprous oxide would crack when the units were straightened out under pressure. Later, however, it was found that this amount of bending of the units was not important so that it became possible then to reduce the thickness of copper from 1/8 inch to 0.05 inch, and later to 0.04 inch in the large units, and even to thinner sections than that for small units.

7. *Methods of Removing Black Oxide.* On account of the high resistance of the

cupric oxide layer which forms during the cooling of the disk from the oxidizing temperature, it became necessary to remove this layer. This was first done by grinding, later by sandblasting and by abrading with emery cloth, and finally by chemical solution. The first chemicals used for the solution of the cupric oxide were sodium or potassium cyanide. This was later changed to the use of mineral acids, which is the present practice.

8. *Methods of Making Contact to the Free Surface of the Cuprous Oxide.* This was considered a very important detail, because the forward resistance of the unit depends on the use of the entire cuprous oxide surface for the conduction of the useful current. It was, therefore, necessary to provide a contact that would reach into the depressions of the mat surface of the cuprous oxide, resulting after the removal of the black oxide. This contact was first made by applying a deformable metal such as lead. It was found that in operation the lead reacted with the cuprous oxide and reduced a part of the compound to copper, which made poor contact under these circumstances and increased the forward resistance. This condition was improved by applying a thin coat of tin to the lead, thereby reducing the reactivity of the material with the cuprous oxide. Later a more continuous contact was made by rubbing carbon or graphite into the surface of the cuprous oxide before applying the front contact. Still later this continuous contact was produced by painting the front surface with a suspension of carbon or graphite. Other methods of making contact have since been developed, such as reducing a portion of the cuprous oxide to copper and then electroplating over the copper with nickel. This produces a very satisfactory contact that is independent of atmospheric moisture, and which has very satisfactory low resistance. Another type of contact that is used on small rectifiers is made by allowing evaporated gold to condense on the cuprous oxide.

9. In the contacts that depend on a deformable metal for continuity, it is necessary to apply pressure. This is done in the disk assemblies by means of pressure applied by the bolt which holds the assembly together. Rather surprisingly it was found that pressures up to 1, 2, or even 3 thousand pounds per square inch can be applied to the cuprous oxide without injury, provided only that it is fairly uniformly distributed. This pressure has to be maintained during the life of the rectifier, and on account of variations in the length of the bolt and in the thickness of the disks due to temperature changes, it became necessary to apply the pressure through springs or spring washers that could take up such irregularities.

Figure 7. D-c volt ampere characteristics of $1^1/_2$ inch disks

Figure 8. Range of reverse resistance using same copper

10. *Check of Different Kinds of Impurities in the Copper.* This became a very difficult problem which has been under study since 1921, and is still only partially solved. More will be said about that in later paragraphs.

11. At the beginning a great deal of experimentation had to be done to determine the appropriate operating voltages per disk and appropriate current densities. The effect of voltage, current, temperature, pressure, and other conditions on the life of the rectifier and the rate at which they would change with time became problems that have been under continous observation during the last 25 years.

After a few years of development some phases of rectifier production had been fairly well standardized. Washers were almost exclusively used for convenient mounting on bolts. Thirteen to fifteen minute oxidation was used universally. Carbon and lead were used for the contacts. A Chile copper prepared for rectifier production by special rolling processes was used universally because it produced the most consistently satisfactory results. Fifty-mil copper, with the least possible percentage of impurity and with a surface prepared suitable for polishing, was used.

The requirements that we had learned to consider essential were the following:

1. The lowest possible forward resistance and the highest possible reverse resistance.

2. Permanence, both in the forward and in the reverse resistance characteristics.

Both of these conditions have improved continuously as the development has progressed, and it would be interesting to plot a curve of each characteristic against time during which the development has taken place. Such a curve, however, is not easily drawn because the methods of testing have also changed continuously, and it is difficult now to correlate the recent test results with the early test results.

In the search for low forward resistance it was soon found that the rate of cooling had an important effect. If the disks were cooled in a blast of air instead of in still air, the forward resistance was lowered. The success of the air blast suggested the investigation of still more rapid methods of cooling, and the next step was the application of a very fine water spray. It was still considered necessary not to cool too rapidly because that might result in the cracking of the cuprous oxide crystals. The fine water spray produced further improvement, and it was finally decided to quench the disks in a water bath, and this resulted in still further improvement. It was then realized that there might be a possible optimum temperature from which to quench the disks. Another furnace was provided which has since become known as the annealing furnace, in which the rectifiers were placed after oxidation to bring them to definite temperatures from which the quenching could take place. It has been found that quenching for best results has to take place from a definite temperature, and that the length of anneal at this temperature is also very important. Even the rate of cooling between the oxidizing furnace and the annealing furnace is important. Quenching has the effect of reducing the forward resistance by a very large amount, and without having a corresponding effect on the reverse resistance so that the rectifying ratio and the quality of the rectifier for most applications is improved. The quenching has therefore become standard practice, except for very high resistance rectifiers for special applications, Figures 4 and 5.

Another condition that became exceedingly important as time went on was the presence of different impurities in the copper. Many suggestions have been made to explain the fact that Chile copper was more satisfactory for the production of rectifiers than any of the domestic coppers. It is not possible here to go into a discussion of all these suggestions, or to describe all the experiments that have been made in an attempt to determine what were the beneficial and what were the injurious impurities. It is definitely known that some impurities are valuable; for instance, it has been proved on many occasions that copper that contains approximately 0.03 per cent of oxygen is more satisfactory for rectifier production than are coppers with a greater or a lesser oxygen content. At one time it was believed that silver in the copper was very injurious, and that the reason that Chile copper is better than domestic coppers was that it contained less silver. At one time it was also believed that the presence of lead in the copper was an advantage, and an attempt was made to get copper with certain percentages of lead. Neither of these conclusions have been verified in the long run, and it is probably true that a small amount of either lead or silver is an advantage in most types of rectifiers, but that a larger amount, which may not be more than a few thousandths of 1 per cent, is definitely injurious. Thousands of experiments over many years have resulted in the acceptance of the following generalizations. Small amounts of metallic impurities increase the resistance of the rectifier in both directions, and may result in an increased stability of the reverse resistance. Nonmetallic impurities decrease the resistance in both directions, and result in a decreased stability of the high resistance, but also in a decreased amount of aging in the low resistance. Both types of materials have an effect not only on the resistance of the cuprous oxide itself, but on the resistance of the junction. The ideal toward which many have striven is to get as pure copper as possible to begin with, and then to add the

impurities that are necessary to get the characteristics required.

This has not been entirely successful, but in production at the Union Switch and Signal Company advantage is taken of such a program in the following manner. To increase the reverse current stability and the reverse resistance under operating conditions, a very small amount of iron is plated on the surface of the blank before it is oxidized. To decrease the forward resistance, which is largely located in the body of the cuprous oxide, the oxidation is allowed to take place in two stages: First, in a furnace is which the atmosphere is pure air, and second in one in which the atmosphere is pure air with a very minute addition of chlorine. This gives us a great amount of control of the characteristics of the final units in that we can vary the amount of iron, and we can vary the percentage of chlorine and also the length of oxidation in each of the two furnaces.

Another method of control that enables us to vary the characteristics is to combine with the use of these addition agents a variation in the temperature of oxidation and in the rate of cooling. Thus the cooling can vary from a slow cooling in still air to cooling in an air blast or to cooling in a water quench with all possible gradations between any two of these three conditions.

At this point I wish to show a set of curves of rectifier characteristics to indicate the variations that are possible, and the amount of control that is available in copper oxide rectifier production.

Figure 6 shows d-c volt ampere characteristics of three types of rectifiers; one high resistance, one low resistance, and one intermediate. The intermediate type is the kind of rectifier that is commonly in use for power applications such as battery charging, other electrolytic work, and the operation of small motors. The high resistance unit would be especially suitable for use in very high-voltage rectifiers where the current requirement is low. The low-resistance rectifier, on the other hand, might find uses where the output voltage requirement is low, say two or three volts, and the current requirement is comparatively high. It will be seen that the difference between the high-voltage rectifier and the low-voltage rectifier is a factor of three or more in resistance both in the high resistance direction and in the low-resistance direction.

Figure 7 shows two similar characteristics representing rectifiers made from the same kind of copper with the difference that the high-resistance unit is made with the addition of iron but no chlorine, and the low-resistance unit is made with the addition of chlorine and no iron. Both are water quenched. It will be seen that the variation in characteristics is quite large, and any intermediate value can be obtained by varying the amount of chlorine or iron.

Figures 8 and 9 represent reverse and forward resistance voltage characteristics for disks made from the same copper, both made with chlorine and no iron; the high resistance unit being cooled in air and the low-resistance unit being water quenched. Again it is seen that control over a wide range of characteristics is available.

Methods of Testing

Another interesting chapter in the development would describe the methods used in testing the rectifiers to determine their quality and their usefulness in various applications. The correlation of test results with service behavior has been a very serious problem. In the early stages of the development, all tests were made at two volts, and all rectifiers were rated on the basis of forward resistance at two volts, and the reverse resistance at two volts, or in terms of what was known then as the rectification ratio, which is the ratio between these two resistances.

After some time it was realized that the reading of forward resistance at two volts does not tell the whole story, because the forward voltage in service is usually of the order of 0.5 instead of 2, and the reverse voltage in service is often of the order of

Figure 9. Range of forward resistance using same copper

six volts instead of two. The testing was then changed to the use of 0.5 volt and later 0.5 ampere in the forward direction and six volts in the reverse direction. The tests were still made by taking readings as quickly as possible on the test instruments. Later the reverse voltage used in the tests was raised to 10 volts. After many years it was realized that these quick tests did not correlate with the service performance of the disks. Sometimes a rectifier that seemed very unsatisfactory and that would be thrown out on the basis of quick tests was found to be entirely satisfactory in a service test. The problem then was to find a quick test that would correlate better with service performance, and after a great deal of search and much experimentation it was found that a quick test with the units at 70 degrees centigrade correlated very much better with service performance than did the test at room temperature. Even this was not entirely satisfactory, and is now supplemented by a stability test which consists in mounting sample disks in a stack and applying six volts d-c per disk for 24 hours. This test gives very good correlation with service performance, and can be used as a definite indication of the quality of copper oxide rectifier disks.

Life tests are obviously a very difficult problem because the rectifier lasts so long that a life test cannot be used as a guide in production. It has been found, however, that there is a definite relation between the life test performance at higher temperatures and the life test performance in service. This correlation is not absolute, but is good enough to give valuable information in a few weeks as to the performance that can be expected by a rectifier in service for many years. The reason that life tests are so difficult is that the rectifier itself has a very long life, in power applications, at least 20 years, and in other special applications probably at least 50 years.

Growth of Production

During the 25 years under consideration the copper oxide rectifier has enjoyed a steady increase in the number of applications and the quantity produced and used. The rectifier has a very wide range of applications both from the standpoint of types of service and from the standpoint of size and capacity. It has been used in applications from radio detection and instrument rectifiers to modulation and demodulation circuits in radio, and in carrier telephony, and to a wide variety of power applications. It has found many auxiliary uses which are based on the voltage or current characteristics of the units, such as the absorption of energy in magnetic coils and the snubbing of relays, the control of pick-up time and release time of relays, click reducers in telephones, polarization of circuits and of neutral apparatus. For these purposes the units have varied in capacity from a few microamperes, in disks that are only 0.03 inch in diameter, to currents of 25,000 to 100,000 amperes in plating rectifiers, and from microvolts to 1,500,000 volts in rectifiers used for radio detection or instruments at one extreme to voltages for experiments in atomic physics at the other extreme. The sizes of the units vary from vest-pocket editions that contain only a few milligrams of copper to units that weigh many tons. The power capacities vary from microwatts to kilowatts. The consumption of rectifiers during the last few years may be illustrated by saying that the amount of copper used in rectifier production is estimated to be between 1,500 and 2,000 tons per year. Without special provision for ventilation 2,000 tons would correspond to approximately 500,000 kilowatts of capacity per year. This capacity is very much increased by the fact that many of the units are provided with forced ventilation, so it can be assumed this estimate is conservative.

This very rapid review of the history of the copper oxide rectifier from its beginnings to the present time shows how it has grown from a single and very inefficient laboratory unit to an efficient rectifier extensively used in all phases of the electrical industry, and corresponding to that use, how it has grown in production to a sizable industry of its own. The development of such a unit is an exceedingly slow process for many reasons, and especially because it takes so long to determine whether a new type is or is not an improvement. Many research men and engineers in this country and abroad have been engaged in the development. All are agreed that there is still much to learn and, with the improved tools provided by the extensive research in semiconductors and the consequent better understanding of the behavior of materials in the solid state, the prospect is even more interesting than before, both from the practical and from the theoretical standpoint. It has been a pleasure to review and to tell the story, and those of us who have been active in the development appreciate very much the interest shown in it by the metallic rectifier subcommittee and by the AIEE.

No Discussion

A Bridge Method for Determining the Motional Characteristics of Permanent-Magnet Movable-Coil Instrument Mechanisms

R. W. GILBERT
ASSOCIATE AIEE

Synopsis: The instrument mechanism is expressed in terms of an equivalent electric network, and the apparent electrical parameters determined by a-c bridge methods. The extracted parameters are: the apparent series resistance, the apparent damping resistance, the undamped period, and the periodicity at which the phase angle of reactance to the shunt resistance is −45 degrees. From these the periods and damping coefficients can be calculated. By including the d-c deflection sensitivity of the instrument the moment of inertia and the restoring torque gradient also can be calculated.

IN the design of d-c instruments motional characteristics such as period and damping sometimes must be accurately controlled. In production it may be desired to measure these factors conveniently for specification compliance. An example is the standard "VU" meter wherein the nature of the instrument's response is intimately associated with sound monitoring technique, and must be specified and controlled in production. In a completed and highly damped mechanism measurement by direct observation is not sufficiently accurate for inspection purposes, and examination formerly required at least partial disassembly.

During the course of some bridge measurements on a sound transducer in various acoustic surroundings by established methods, it became apparent that a similar technique could be applied to the analysis of instruments. The time parameters in this case are much longer but the mechanism is similar. As the method and theory developed, it further became apparent that more information than first anticipated could be extracted, specifically the mechanical parameters of torque and inertia.

The method here described pictures the instrument as a simple damped reactive electrical network, and measures its apparent electrical parameters by means of an a-c bridge. From the values thus assigned to the network the actual time and mechanical parameters are calculated.

In a companion paper[1] W. N. Goodwin, Jr., has developed the mathematical relationship between the mechanism as a mechanical system and its apparent electrical parameters. He therein also proves that the measurement is valid regardless of the nature of the interposed resistance network, if linear. These therefore are assumed evident, and the present paper is limited to the method of measurement, supported by theoretical description only as required in the course of explanation.

Terminology

The following terms are used in the discussion:

L,L' = apparent inductance, equivalent instrument network, henrys and abhenrys, respectively
C,C' = apparent capacitance, equivalent instrument network, farads and abfarads, respectively
R_f,R_f' = apparent internal damping resistance, equivalent instrument network, ohms and abohms, respectively
R_e = apparent series resistance, ohms
R_0 = critical damping resistance, total, ohms
T_p = periodicity, a-c bridge source, seconds per cycle
T_a = amplitude period, instrument, seconds per cycle
T = damped period, instrument, seconds per cycle
T_0 = undamped period, instrument, seconds per cycle
T_1 = periodicity, for −45° phase angle of R_f and C_1, seconds per cycle
C_1 = effective capacitance, instrument, for −45-degree phase angle against R_f
P = bridge ratio, numeric
K = moment of inertia, instrument, gram centimeters squared
S = control torque, instrument, dyne centimeters per radian
B = air gap flux density, gausses
A = effective movable coil area, square centimeters
N = number of turns on movable coil
q = attenuation ratio of resistance network, numeric (unity for unshunted instrument)
I' = current sensitivity constant, instrument, abamperes per radian
η = specific damping coefficient numeric

Equivalent Network

It is well recognized that resonant mechanical and electric systems are rigorous analogues of each other, and are expressible in similar, and even identical, terms. Furthermore, the permanent-magnet movable-coil mechanism such as a d-c instrument includes electromechanical coupling and appears as an electrical resonant network at the terminals. In this case the analogue becomes also an equivalent and may be measured as such. This equivalence has been of particular value in the analysis and expression of

Paper 48-67, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted October 31, 1947; made available for printing December 23, 1947.

R. W. Gilbert is with the electronic engineering division, Weston Electrical Instrument Corporation, Newark, N. J.

The calculations in considerable part were derived from the basic work of W. N. Goodwin, Jr. (F '13), particularly in relating the electrical to the mechanical parameters. Also, the assistance of F. V. Masson who designed and built the bridge of Figure 3 is appreciated.

Figure 1. Equivalent network of movable coil instrument

electroacoustic transducers, to most of which the d-c mechanism is similar, but which have parameters of a considerably different order of magnitude.

The permanent-magnet movable-coil mechanism may be expressed by the equivalent circuit and the elements of Figure 1. It is essentially a parallel resonant inductance L and capacitance C shunted by a loss resistance R_f, and connected through a series resistance R_c. These particular elements may not have exact physical counterparts in the mechanism, but any mechanism is expressible in these terms so that the mechanism and its equivalent circuit are ideally indistinguishable at their terminals.

In terms of electromechanical equivalence the capacitance C represents the moment of inertia, the inductance L the spring compliance (reciprocal torque), and the resistance R_f the loss both frictional and electrical. The series resistance R_c is the terminal d-c resistance, which in unshunted instruments is the movable coil resistance. Note in contrast that general electromechanical analogues associate capacitance with compliance and inductance with inertia, whereas the reverse is true here because of the inversion produced by electromagnetic coupling.

The instantaneous position of the instrument pointer is related directly to the force level in the spring compliance, which is equivalent to the current in inductance L. This relationship is useful in determining the nature of the pointer response to complex or nonrecurrent input wave forms or transients. In cases difficult to calculate a "mockup" of the network using electric components will make an oscillographic determination possible. In such an experimental determination it may be necessary to "scale-up" the order of frequency, which is permissible if the ratio $(L/C)^{1/2}$ is maintained in relation to the network resistances.

It is broadly apparent that when a mechanism is expressed in terms of its equivalent network, powerful tools for its analysis exist in available methods for network treatment, both theoretical and experimental. No comparable treatment appears to exist in direct mechanical analysis. This is strongly evident in the present trend toward electrical analogue computation of mechanical problems as a matter of practical convenience, and conventional methods for specific problems are too detailed and extensive for presentation here.

Electromechanical Flux Linkage

In the d-c mechanism the electric input is coupled to the mechanical motion of the system through the force-current reaction of the movable coil in the magnetic field. Coil current causes a mechanical force, and in reciprocity coil motion causes a potential reaction, both being dependent upon the subtended magnetic flux, or "flux linkage." In the usual case of a coil pivotally suspended within a uniform radial flux field the flux linkage may be expressed as the product of flux density B, the coil area A, and the number of coil turns N; the so-called "BAN factor."

In the equivalent network the flux linkage would appear as an ideal transformer of turns ratio BAN connected between the actual mechanical sources of L and C, and the resistances. The corresponding impedance ratio is $(BAN)^2$. This transformer cannot alter the resonant frequency, so the LC product remains constant, but it will alter the impedance so the L/C ratio is susceptible. Therefore, if it is desired to determine the actual mechanical parameters of torque and moment of inertia from the measured values of L and C, it is necessary to include the BAN factor.

While the separate constituents of the BAN factor are not determinable by external measurement, the BAN factor proper is related to the movable coil current–deflection sensitivity of the mechanism. But the instrument may include a shunting network so that the movable coil current sensitivity is not measurable. It is then necessary to include the attenuation factor of the intervening network q which is the ratio of the movable coil current to the applied terminal current. q is then unity in the case of unshunted instruments and smaller than unity for shunted instruments. The flux linkage factor BAN then becomes an apparent flux linkage factor $(qBAN)$ which cannot be further dissociated without knowledge of the internal construction.

From the basic relationship existing between consistent units, a unit current flowing through a conductor of unit length in a magnetic field of unit density will develop a unit of mechanical force. By simple geometric derivation it is then apparent that a movable coil suspended within a uniform radial magnetic field will develop a torque equal to the product of the coil current and the BAN factor. When equipped with spring restoring force and a possible interposed resistance network

$$S = I'qBAN \tag{1}$$

wherein S is the torque-deflection (rigidity) constant of the spring and I' is the current-deflection constant of the instrument, with the deflection unit expressed in the same term for both, usually per radian.

The $qBAN$ factor has no influence upon the resonant frequency, so

$$L'C' = \frac{K}{S} \tag{2}$$

But the impedance dimensions $(L'/C')^{1/2}$ and $(KS)^{1/2}$ are proportional to the $qBAN$ factor squared, so

$$\frac{L'}{C'} = KS(qBAN)^4 \tag{3}$$

Solution of equations 1, 2, and 3 gives

$$qBAN = I'L' = (I'C')^{-1/4} \tag{4}$$

The $qBAN$ factor is thus calculable from equation 4 by knowing L' or C', and I'.

Damping

The LC circuit of Figure 1 is damped by the loss-resistance R_f. The circuit will be critically damped when

$$R_f(\text{critical}) = {}^1/_2(L/C)^{1/2} \equiv R_0 \tag{5}$$

and for lower values of R_f the system will be aperiodic.

In instrument practice wherein highly damped systems are usual a useful coefficient is the "specific damping coefficient" n which is defined as

$$n \equiv \frac{R_0}{R_f} \tag{6}$$

n is unity for the critical damped condition and zero for the undamped condition. Other useful coefficients of damping are the log decrement and its related expression the "overshoot ratio" k, the latter defined as the amplitude ratio of successive half cycles of free oscillation.

$$\text{log decrement} \equiv \log_e k = \frac{\pi n}{(1-n^2)^{1/2}} \tag{7}$$

Of the time parameters three are of usual interest; the undamped period, the damped period, and the amplitude period, which are defined as follows:

Undamped Period (T_0)—The natural period that would result if the system were loss-free. In networks this is sometimes called

the "phase period," because it is the period of forced oscillation, regardless of damping, at which the reactance parameters cancel and the network appears entirely resistive.

Damped Period (T)—The time interval existing between successive full cycles of free damped oscillation.

Amplitude Period (T_a)—The periodicity of forced oscillation at which the ratio of pointer amplitude to the applied current is a maximum.

Their values in terms of the circuit elements of Figure 1 and the equivalent mechanical expressions are as follows:

Period	Symbol	Electrical Parallel Circuit Expression	Mechanical Expression	
Undamped	T_0	$2\pi\,(LC)^{1/2}$	$2\pi\left[\frac{K}{S}\right]^{1/2}$	(8)
Damped	T	$\dfrac{2\pi(LC)^{1/2}}{\left[1-\frac{L}{4CR_f^2}\right]^{1/2}}$	$\dfrac{2\pi\left[\frac{K}{S}\right]^{1/2}}{\left[1-\frac{(qBAN)^2}{4KSR_f'^2}\right]^{1/2}}$	(9)
Amplitude	T_a	$\dfrac{2\pi(LC)^{1/2}}{\left[1-\frac{L}{2CR_f^2}\right]^{1/2}}$	$\dfrac{2\pi\left[\frac{K}{S}\right]^{1/2}}{\left[1-\frac{(qBAN)^2}{2KSR_f'^2}\right]^{1/2}}$	(10)

The ratio of the damped period T and the amplitude period T_a, to the undamped period T_0 relate to the specific damping coefficient n, as

$$\frac{T_0}{T}=(1-n^2)^{1/2} \tag{11}$$

and

$$\frac{T_0}{T_a}=(1-2n^2)^{1/2} \tag{12}$$

which indicate the convenience of n as a practical expression of damping in relation to the time parameters.

From equation 11 it is apparent that T will become infinite when n becomes unity, and will be imaginary for values of n larger than unity. And from equation 12 the same will occur for T_a when n becomes equal to $2^{-1/2}$ and larger. When T_a is infinite or imaginary the largest deflection of the instrument will occur with direct current.

Note that the damped period and the amplitude period become equal to the undamped period T_0 when n becomes zero, and that at low values of n the separation is small.

Upon consideration it is apparent that a damped system has only one period of natural behavior, its damped period T, and that the other periods result from forced rather than free oscillation to produce certain conditions. But in practical calculations it is considered more direct to express the mechanism in terms of its undamped period T_0 as the time parameter, with n as the damping parameter.

Mechanical Parameters

The mechanical parameters of spring rigidity S and moment of inertia K directly relate to the inductance and capacitance of the network, provided the units are consistent and the interposition of the $qBAN$ factor is included. Thus, by conversion of the network parameters L and C into absolute units (L' and C') and knowing $qBAN$ the mechanical parameters can be determined. Or, alternatively, the current sensitivity I' rather than $qBAN$ may be used as a more direct process.

From equations 1 and 4 by substitution

$$S=I'^2L' \tag{13}$$

which by substitution in equation 2 gives

$$K=I'^2L'^2C' \tag{14}$$

Bridge Method of Measurement

The measurement bridge in functional form is shown in Figure 2. It contains the instrument mechanism as one arm and has a balancing arm comprising the series and parallel resistances, PR_c and PR_f, and a capacitance C_1+P in shunt to PR_f. The bridge ratio P may be large to accommodate the rather large effective values of reactance exhibited by the instrument. The bridge source is alternatively direct current and low frequency alternating current of adjustable known periodicity. The galvanometer serves for a-c balance as well as d-c balance because of the low a-c frequency ordinarily required.

While such a bridge may be manipulated in a number of ways to determine the equivalent network, it is necessary to employ at least two frequencies to extract L and C independently. The present method for convenient calculation determines the undamped period T_0 and the periodicity T_1 at which the apparent reactance is capacitive and has a phase angle of -45 degrees against the loss resistance R_f. At this point the phase angle tangent is unity and the apparent reactance is equal to the loss resistance R_f. This likewise proves to be the point of best bridge resolution with regard to reactance.

The bridge is operated in three steps; determining R_c, T_0, and R_f, and finally T_1, in order. These operations in detail are as follows:

1. With PR_f at zero and the d-c bridge source connected, balance PR_c to establish the series resistance R_c. The PR_c setting thus determined is left unaltered during the following procedures.

2. With C_1/P at zero and the variable periodicity a-c source connected, balance the source periodicity T_s, and PR_f. The instrument will oscillate and must be kept free of the pointer stops and preferably at a small amplitude. The balance point is coincidental to specific values of T_s and PR_f, similarly to a conventional a-c bridge wherein magnitude and phase angle must be independently adjusted. PR_f then represents the loss resistance R_f, and T_s is the undamped or zero phase angle period (T_0) of the instrument. Leave the PR_f setting intact.

3. Decrease T_s (increasing frequency) and add C_1+P to rebalance. Each decrease of T_s can be rebalanced by an increase of C_1+P, and the ability of C_1+P to rebalance the bridge is continuous. Find the balance point where the impedance of C_1+P is equal to the resistance PR_f at periodicity T_s. At this point the tangent phase angle is unity, and T_s represents T_1.

This third operation requires a running

Figure 2. Functional circuit of a-c d-c bridge for measuring instrument parameters

calculation during balancing because both capacitance and periodicity are changing. However, it may be simplified by use of a slide rule to express the relationship at the proper balance point as

$$\frac{T_1}{C_1/P}=2\pi PR_f \tag{15}$$

by setting the slide to $2\pi PR_f$. Balancing may then proceed to the point where the ratio of T_s to $C_1 \div P$ appears on the slide rule.

From T_0, T_1, and R_f as measured, the network parameters of interest may be calculated from

$$T=T_0\left[1-\frac{\left[\frac{T_0}{T_1}-\frac{T_1}{T_0}\right]^2}{4}\right]^{-1/2} \tag{16}$$

$$T_a=T_0\left[1-\frac{\left[\frac{T_0}{T_1}-\frac{T_1}{T_0}\right]^2}{2}\right]^{-1/2} \tag{17}$$

$$C=\frac{T_1T_0^2}{2\pi R_f(T_0^2-T_1^2)} \tag{18}$$

$$L=\frac{R_f(T_0^2-T_1^2)}{2\pi T_1} \tag{19}$$

Figure 3. Complete bridge for instrument analysis, front and rear views

which are modifications of well known resonant circuit expressions.

From equations 11 and 16

$$n=\frac{\frac{T_0}{T_1}-\frac{T_1}{T_0}}{2} \tag{20}$$

and from equations 6 and 20

$$R_0=nR_f=R_f\frac{\frac{T_0}{T_1}-\frac{T_1}{T_0}}{2} \tag{21}$$

At a-c balance distortion products in the bridge source or generated within the instrument mechanism will appear in the galvanometer as harmonics. It is therefore desirable to use a bridge source of fairly pure wave form. Distortion produced within the mechanism may result from nonuniform flux distribution, air or pivot friction, or any interference with free motion such as contacting the pointer stops. Most frictional factors are nonlinear and develop nonlinearity of loss resistance R_f. Nonuniformity of flux distribution in effect causes a modulation of the BAN factor, and is equivalent to a changing L/C ratio, and a changing C_1 for balance.

The foregoing assumes that the capacitors comprising $C \div P$ are free of losses. But at the low frequencies used they may develop an unexpected phase angle as evidenced by an inability to obtain a clean bridge balance in the last operation. In such cases the balance may be improved by slightly increasing PR_f to compensate, but retaining the value of PR_f obtained in the second operation for purpose of calculation.

In some cases it is necessary to deflect the instrument to a desired point on the scale or away from interference by the pointer stops. This requires injection of an additional d-c deflection current during the a-c balancing operations, without shunting the bridge arms. In the bridge of Figure 2 this deflection current may be injected into the galvanometer connection, which is at an a-c nul at balance, with a blocking capacitor to isolate the galvanometer.

Figure 3 shows the constructed form of the Figure 2 bridge as used in the laboratory. By adjustment of the bridge ratio over a considerable range it is possible to measure instruments of all usual sensitivities. It performs all the necessary measurements except the deflection sensitivity I' which is measured directly by observation.

The oscillator used for a-c source is critical regarding purity of wave form and was specially designed for the purpose. It is a modified Scott R-C oscillator with the periodicity adjustable by a dual dec-

ade resistance, which calibrates directly in periodicity rather than frequency. The total harmonic content below the 7th order is less than 0.25 per cent.

Accuracy

The accuracy of the method is limited theoretically only by the resolution of the bridge, which is largely optional. But the practical limit is determined by distortion products obscuring the galvanometer nul. The major distortion in practice arises from magnetic nonuniformity present in some degree in all instruments. Distortion from this source can be reduced by reducing the pointer amplitude, and if necessary increasing the galvanometer sensitivity correspondingly.

So accuracy is primarily a matter of desire and design, with the bridge of Figure 3 a satisfactory mean for most purposes.

The over-all operating accuracy with careful manipulation is considered as 0.5 per cent of the measured values. In the case of highly damped instruments this is far superior to any method employing direct observation, and in any event is considerably more accurate than normally required.

Three-Compartment Articulated Cars for Test on Rapid Transit Division, Chicago Transit Authority

H. A. OTIS
NONMEMBER AIEE

A FEW YEARS AGO, the Chicago Rapid Transit Company saw the possibility of building a vehicle for service on the elevated and through the subway, in the construction and equipping of which many of the parts could be used that had become standard for the Presidents' Conference Committee (PCC) street car. Each of these parts had a definite limitation in its capacity. At that time, the basic train operated on our system during mid-day and at night was two cars so it seemed desirable to include in one vehicle the equivalent passenger capacity. With this passenger capacity and the weight limitations of the equipment in mind a vehicle was designed.

Due to the fact that the vehicle as designed was entirely different from any on our property it was decided to obtain four cars to prove out in actual operation the design and equipment. In order to further the test, two cars were ordered from one car builder and two cars from another. Also, as far as possible, the parts and equipment as installed on the cars as built by one car builder were different from those as installed in the cars by the other builder.

The two cars of one builder have been received and are undergoing test in regular service, while the cars from the other builder are expected soon.

Body and Equipment

Each car has three articulated bodies mounted on four trucks. The length over anticlimbers is 88 feet $7^1/_2$ inches, the middle truck centers are 25 feet 10 inches and the outside truck centers 24 feet $4^3/_4$ inches. In order to hold the weight to a minimum the entire body is made of aluminum except the end underframes beyond the bolsters and the bolsters which are made of steel. The car, complete, weighs 93,000 pounds. The car has a seating capacity of 96, and a total capacity of 250, which is approximately the same as two of our older cars. This is within the weight limitations of the standard PCC motors to give the operating characteristics which we desired.

Dut to structural limitations on the system the width over the side sills is limited to 8 feet 8 inches. In order to obtain greater width at the top of the seat cushion the sides curve out from the top of the side sills to a width of 9 feet 4 inches at seat level height and then back into a width of 9 feet 0 inch at the eaves. Curving the sides out makes possible a 39-inch wide seat and a 30-inch aisle.

A motorman's cab is built in at the right-hand corner of each outside end of the car. This cab contains the power and brake controllers, an enclosed switchboard at the rear of the cab, a gang of operating switches and a side entrance door control switch.

At each articulated joint there is an open archway in each body which permits uninterrupted passage from one compartment to another. The space between bodies is closed by a canvas diaphragm fastened to both bodies. At the outside ends are train doors which permit passage between cars.

Built into each end of the car are two headlights, a curtain destination sign and four illuminated combination tail and classification lights having four colors in each.

The motorman's front cab window is equipped with an electric windshield wiper and inside window defroster both with speed control.

The side windows are raised and lowered by means of automotive type operators with the cranks located above the windows. All windows raise and their travel is limited to eight inches. All glass throughout the car is safety sheet except that in the front cab window which is safety plate.

The car lights are single fixtures of the controlled-beam type, one located over each seat. The lamps used are the 20 in series 30-volt 1-ampere short-circuiting type. The lights are remotely controlled and can be turned on or off on the whole train from any motorman's cab or a switchboard on the center compartment.

The seats are all 35 inches wide, set perpendicularly to the side of the car and upholstered in mohair. The seats are stationary and set so that one-half of the passengers ride backwards. The side wall of the car between window posts and from the bottom of the window to below the top of the seat cushion is cut back to about one inch thick. The edge of the seat cushion is set four inches from the side wall which in effect gives a seat cushion 39 inches wide.

Drawbars

The drawbars are M. C. B. (Master Car Builders) tight lock type and furnished by the Ohio Brass Company. Attached to the bottom of the head is an electric circuit coupler portion with 56 contacts. The drawbars can be uncoupled by pressing a button located either in an adjacent motorman's cab or under the car body end sill near the side of the car. The pressing of any of these buttons starts a progressive action that

Paper 48-64, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa. January 26–30, 1948. Manuscript submitted November 14, 1947; made available for printing December 17, 1947.

H. A. Otis is engineer of car equipment, Chicago Transit Authority, Chicago, Ill.

opens the electric jumper circuits by throwing a drum switch on each car, starts a hydraulic pump which forces fluid into a cylinder through which a moving piston pulls back the drawbar lock to complete the uncoupling.

Heating and Ventilation End Compartments

The traction motors accelerating and braking resistors are enclosed the same as on the street cars and the waste heat from them is used to help heat the car. Each compartment is equipped with a motor generator set to supply the power for the low-voltage circuits. The motor generator sets also have a two section blower mounted on each end of the shaft. Each one of these blowers draws 425 cubic feet per minute (cfm) of air out of the car body through a grill in one of the center door posts and 325 cfm of outside air through a grill and register located in the outside of the center door post directly across the car. These two volumes of air are mixed together in the blower and are forced into the resistor enclosure. Thus, the two blowers together exhaust 850 cfm of air out of the body, mix it with 650 cfm of outside air and force the 1,500 cfm of mixed air into the resistor enclosure. While passing over the enclosed resistors this air becomes heated and passes out through a duct at the bottom of the enclosure. In this duct is a motor-driven damper which either exhausts this air to the atmosphere or into the car body.

Temperature thermostats are located in the duct containing the air exhausted from the car body. If the temperature of this air is below the setting of the thermostat it closes a circuit to cause the damper motor to move the damper which sends more hot air into the body. If the temperature of the return air is above the setting of the thermostat it closes a circuit to cause the damper motor to move the damper to exhaust more of the heated air. The exhaust air is conducted through ducts to the space between the compartments and there exhausted to the atmosphere. The heated air being directed to the interior of the body passes over electric heaters and a thermostat set at 100 degrees fahrenheit. If the temperature of the air going to the interior of the body is not up to 100 degrees the electric heaters are turned on to bring up the temperature. Air going to the interior enters four longitudinal ducts in the floor. Air from these ducts then enters the body through louvers on each side of each aisle seat pedestal and through grills in the side wall below the seat cushions. The circuit of the damper motor contains a time-delay relay which makes the motor circuit a pulsating circuit and causes the damper to move slowly toward either the open or closed position.

Above a flat section of ceiling at the articulated end a motor is located driving two blowers that draw in outside air through grills in the roof, pass the air over electric heaters and into longitudinal ducts in the ceiling, from which it is exhausted into the car. In the duct is a thermostat set at 50 degrees that controls the electric heaters to bring the temperature of this outside air up to 50 degrees before entering the car. In series with the motor of this blower, there is a rheostat connected to the dump damper under the car and so arranged that as more heated air is exhausted to the atmosphere, the speed of the overhead blower is increased by reducing the resistance. In the ventilating system under the car, a fixed amount of fresh air is taken into the system. When some of the heated air is exhausted to the atmosphere it carries with it a proportion of the outside air taken in. The overhead fresh-air system makes up for the fresh air in the underneath system that is being exhausted. Also, during hot weather when all of the hot air is being exhausted, the overhead system runs at its maximum speed and forces cool outside air in at the ceiling line where the hot air tends to collect.

With the accelerating and braking resistors enclosed it is necessary that the motor generator set be in operation at all times that the car is in operation. Advantage was taken of this fact to eliminate all heating and ventilation switches and control. Whenever the motor generator sets are in operation circuits are set up and the heating and ventilation are entirely automatic under the control of the thermostats.

Center Compartment

There are no accelerating and braking resistors on the center compartments so that the entire heating must be done by electric heaters. As on the end compartments, air is drawn out of the interior by a blower on the shaft of the motor generator set, is passed over the electric heaters in an enclosure, and back into the body through the seat pedestals and grills in the side walls. Thermostats located in the air stream control the electric heaters and also a motor that varies the resistance in series with the overhead fresh-air intake-blower motor. The amount of fresh air introduced at the ceiling depends upon the temperature of the interior air. The minimum speed of this intake blower is sufficient to furnish 10 cfm for each seated passenger.

Side Entrance Doors

On each side of each compartment there are two entrance and exit doors separated by a post. Each opening consists of two inwardly folding doors of the PCC type, that when open provides a 24-inch passage. These doors are electrically driven and may be remotely controlled in any desired combination from a number of different operating positions. Door operating positions are in each motorman's cab and between the side entrance doors in each center compartment. By the operation of zone switches located on the switchboard in each motorman's cab any desired combination of side doors may be controlled from any operating position.

In each motorman's cab there are signal lights which are lit when all side doors are closed and out when any one door in the train is open. Thus, when the signal lights in the operating cab are on, the motorman may start his train. Above each group of side doors, there is a light which is on when either door at that position is open. This light has a red lens to the front and rear to give an indication when the door is open and a clear lens on the bottom to light the platform near the door. The positive feed to the master controller in the operating cab is through a relay in the side door signal circuit, so that when any one side door in the train is open, the control-positive feed to the operating controller is open.

Trucks

The trucks are basically the same as under the PCC street cars except that due to the heavier king-pin loads, it was necessary to strengthen all parts. The principal changes were the increase in the diameter of the resiliant wheels from 25-to-28 inches in order to obtain more rubber, the use of a $5^1/_8$ inch wide wheel and a 5 inch instead of a 4 inch diameter axle. The railroad's standard third-rail current-collecting device is attached to the truck.

Propulsion Motors

The motors on these cars are standard PCC street-car motors mounted lengthwise of the trucks and connected to the axles through hypoid gearing. The motors are force ventilated with air furnished by a section of each blower on the motor-generator set shaft. These motors, as on the street cars, not only furnish the power

for propulsion but also through dynamic brake circuits also stop the car.

Motor Control

The motor-control equipment also is nearly the same as on the street cars, the only difference being those changes necessary to make the control multiple unit. The amount of current flowing through the motors in both propulsion and braking, and thus the rate of acceleration and braking, is under the control of a current-limit switch. On the street car the spring which controls the amount of current through the limit switch is connected to the operator's position by levers and rods. The operator can obtain an infinite number of settings of the spring and thus the rates of acceleration and deceleration. For multiple-unit operation three fixed rates were selected for both, and they are obtained by passing a fixed amount of current through three different coils on the limit switch which in reality stretches the limit-switch spring three different amounts. The rates of acceleration and deceleration which were selected correspond to approximately one, two and three miles per hour per second.

The master controller, located in each motorman's cab, contains a central coasting position with the acceleration positions to the right of the coasting position corresponding to the three rates of acceleration and with four positions of braking corresponding to the three rates of braking and an emergency rate to the left of the coasting position.

A motorman in the operation of this train, after noting the door-signal light is on places the controller handle in the position to give the desired rate of acceleration, namely one, two or three miles per hour per second. After the train has obtained the desired speed the controller handle is placed in the coast position. When it is desired to stop the train, the controller handle is placed in the position to give the desired rate of retardation and left in that position until the train stops. When the controller handle is placed in the coast position the braking circuits are set up so that retardation is obtained at once, when the controller handle is moved to the braking position. The motors act as the sole brake until the speed is reduced to just a few miles an hour, when the dynamic brake fades out due to the low-generated current of the motors. At the current setting of a relay called the lock-out relay, the dynamic-motor circuit is opened and the drum brake on the motor shaft is applied, which brings the train to the final stop.

When the controller handle is placed in a braking position and current flows through the dynamic-braking circuits the motors act as a brake and the lockout relay prevents the armature-shaft drum brake from being applied until the current through the motors drops below the setting of this relay. Should current fail to flow through the dynamic-brake circuit, the armature-shaft brake comes on automatically. This armature-shaft brake will also give decelerating rates of approximately one, two or three miles per hour per second depending on the amount of current through the application coil.

Attenuator Materials, Attenuators and Terminations for Microwaves

G. K. TEAL
NONMEMBER AIEE

M. D. RIGTERINK
NONMEMBER AIEE

C. J. FROSCH
NONMEMBER AIEE

THE INCIDENCE of the last war gave rise to demands for radar and communication systems requiring the development of a large variety of microwave devices. A considerable number of these employed "lossy" solids that we have called attenuator materials since they may differ considerably from those solids normally classed as resistor materials. Many engineers at the Bell Laboratories were engaged in various phases of the development of such circuit elements.[1] Although the present paper discusses the development primarily from the materials point of view, the related problem of design was one that could not be separated entirely from the materials aspects and, therefore, is touched upon too.

While it is not intended to present a review it may be of interest to mention other work in the field. The pioneering experiments in the field were done by Southworth, Bowen, King, and their coworkers.[2] More recently, valuable high frequency applications have been made of the deposited carbon resistor as developed in these laboratories by R. O. Grisdale and his coworkers[3] and of the evaporated metal film of the Polytechnic Institute of Brooklyn. Much work on attenuating devices was carried out in other research centers, particularly at the Radiation Laboratory.[4] The materials discussed in the following paragraphs differ from these and were developed primarily to meet the requirements of high power usage in radar systems. At the time the needs arose there were virtually no attenuator materials available for many new applications. The shortcomings of the few known materials fell into one or more of the following categories:

1. They were unable to handle the available power.
2. The methods of preparing them did not permit standardization to give dependable electrical characteristics.
3. They were not stable.
4. They were not suited to giving the desired physical configuration.
5. They did not permit the attainment of some special characteristic that was required for a specific job, for instance, constant attenuation with absorption of high power.

In Figure 1 are shown in simplified form two microwave systems to illustrate typical uses of attenuator materials. In the case of the measuring equipment shown in (*a*) a signal generator is sending radio frequency signals *A* of a few centimeters wave length into a metal wave guide. Normally the signal generator is protected from reaction from the remainder of the system by a pad *B* of 10 to 30-decibel attenuation inserted at this point to stabilize the oscillator against variations in frequency caused by changes in the load impedance. In order to adjust the output level of the signal by measurable amounts or to reduce it to a conveniently measurable level a variable attenuator *C* is provided in the circuit at the point shown. It is followed by the material or device whose characteristics are to be determined. Another variable attenuator *D* may be inserted between the material under study and the receiver *E* to permit adjustment of the output level. The receiver is a sensitive element, such as a thermistor or detector, which is actuated by the output signal.

The case of a radar system is illustrated in (*b*) of Figure 1. Since the output of this system should be as nearly the maxi-

mum output of the magnetron generator as possible, the attenuation in the wave guide is reduced to a minimum and the antenna which radiates the beam into space is designed to give a minimum reflection of the signal back towards the signal generator. Sometimes, however, conditions may arise leading to the reflection of an appreciable part of the signal. The magnitude of the reflected power can be determined and the output monitored by means of a directional coupler.[4,5] Such a directional coupler employs terminations in a manner permitting the magnitudes of the signal and reflected waves to be separately determined by measurements at the probes P and P_B, respectively. Thus, for instance, known portions of the signal and reflected waves enter the lower chamber through apertures, the signal portion proceeding to probe P while the reflected portion is absorbed by the termination shown. In the upper chamber the situation is reversed, the signal portion being absorbed, while the reflected portion is determined at P_B. It is general practice during tune up of a radar system to replace the antenna by a dummy antenna consisting of a termination that will effectively absorb all the energy normally radiated. This is necessary to reduce interference between systems and to prevent the detection by the enemy of radiated power during tune up. To permit tune up the dummy antenna must absorb the full output of the transmitter peak power from 50 kw to more than a megawatt and average powers of 50–1,200 watts. The great difference between peak and average powers is due to the pulsing of the radio frequency with short duty cycles.

The more important applications of the attenuator materials to be described proved to be terminations for dummy antennas and for directional couplers, primarily for moderately high and very high powers.

Practical and Theoretical Considerations Governing the Present Development

General Requirements of Attenuator Materials

In Table I are listed several characteristics sought for in the materials and designs investigated. It is necessary that the attenuation be high and that the termination shall reflect negligible amounts of the signal. The material should be chemically stable, should not be warped by heat, and should conduct the heat readily from inside the guide to the exterior. For quantity production the characteristics must be readily reproducible and, to minimize the number of necessary materials it is desirable that the one chosen shall be sufficiently adaptable to permit its fabrication in a variety of designs. Since space is often at a premium the material should permit compact designs.

The needs for attenuators made it necessary to examine materials giving a wide range of attenuation values. Low temperature coefficients of attenuation are needed in some cases. In general, water absorption should be minimized since a high attenuation may result due to a strong resonance absorption of radiation by water in the frequency region of interest. Moreover, this attenuation may be variable either because of a change of the number of absorbing molecules in the wave guide or due to a mechanical warpage of the attenuator material out of its normal position in the guide. Also it is sensitive to frequency and temperature.

Classification of Materials Studied on the Basis of Their Physicochemical Structure

From the point of view of the structure there are two general classifications of attenuator materials: Lossy dielectrics and resistor strips.

Homogeneous dielectrics have been used as attenuator materials. They have serious drawbacks, however. Those like polystyrene, methyl methacrylate, and bakelite do not attenuate waves strongly and there are no suitable means of controlling the loss. The materials with higher loss, such as water, exhibit their loss through molecular resonance, resulting in attenuating properties sensi-

Table I. General Characteristics Desirable in Materials and Designs

For terminations
1. High attenuation.
2. Low reflection of energy.
3. Ability to stand high or moderate power without deteriorating.
(a). Good chemical stability.
(b). Good geometrical stability.
(c). High heat conductivity.
4. Good reproducibility.
5. Adaptable from the fabrication point of view.
6. Compact.
Additional characteristics important for attenuators
7. Wide range of attenuation values.
8. Low temperature coefficients of attenuation.
9. Low moisture absorption.

tive to temperature and frequency. The solids described herein avoid some of these drawbacks and, it is believed, more nearly meet the requirements of commercially useful materials. They are dispersions of conducting or semiconducting particles in low loss solid dielectrics. Materials employing ceramic, plastic and rubber bonds have been investigated. The d-c conductivity and other attenuating properties of these materials depend on a number of factors such as: The volume content of semiconductor, the specific resistances of the bond and semiconductor, the particle shape, particle size, dispersion of the particles in the bond, and the methods of making the composite solid.

For the second type of attenuator material cited, a resistor strip, similar combinations of such solids can be employed as films on ceramic, mica, or plastic supports. The bond is normally a plastic.

Although the physical structures of these materials appear very similar the properties obtainable are widely different, the methods of employing them vary considerably and the chemical methods of fabricating them cut across the four rather well established technological fields of ceramics, plastics, rubbers, and finishes.

General Influence of the Dielectric Properties of Solids on Their Application as Attenuator Materials

It is of interest to consider the influence that some of the more fundamental properties of the materials may have on their application. In Figure 2a is shown a metal wave guide filled to the right with a lossy dielectric and to the left with air. A wave traveling to the right is partially reflected on encountering the dielectric while the remainder enters the solid and is attenuated by it. The portion of the wave reflected may be determined from measurements of the maximum and minimum voltages of the standing wave resulting from superposition of the signal and reflected radio frequency. The losses due to dielectric absorption and reflections are important considerations and were subjected to much study. Moreover, reflections that are too small to be serious from the point of view of loss are often of great importance because of the influence they may exert on the mode of operation of a microwave oscillator.

For the disposition of dielectric shown it is possible to determine the impedance of the dielectric filled portion and from this the dielectric constant and tangent of the loss angle. With these data it should be possible, by application of electromagnetic theory, to calculate the reflections and attenuation due to a piece of attenuator material of arbitrary but known geometry in a wave guide. However, due to the difficulties of making measurements of the dielectric constants of high loss materials, because the theory of tapered structures is complex and not well developed, and because the calculations are laborious it was necessary to carry out the present development largely empirically.

It may be helpful, however, to consider the relationships between the fundamental constants of a solid and its suitability as an attenuator material. In Table II are shown some calculated values of loss per wave length for several materials to show the way the magnitudes depend on the tangent of the loss angle and the dielectric constant. In a termination it is necessary that the loss should be of the order of 40 decibels to reduce the signal to negligible magnitude and to prevent appreciable reflections from behind the termination from appearing at the signal generator. For compactness it is desired that this be obtained in as few wave lengths as possible, consistent with meeting the requirements as to reflections. Losses per wave length of 15–20 decibels or greater are desired. Materials such as polystyrene, bakelite, transite, steatite, and porcelain, according to measurements made at 10 centimeters, fall in the lower ranges of loss shown here and are unsatisfactory. Water has a higher loss factor and dielectric constant and gives a loss falling in the higher range indicated in the table but seems unsatisfactory for a variety of reasons, some having been indicated in previous sections. As can be seen, the loss requirements of the materials of interest for terminations must have tan δ values of 0.1 to 1.0 or even more or else have dielectric constant values greater than 40.

The reflection from a lossy dielectric increases with increasing dielectric con-

stant and tan δ and is more sensitive to changes of dielectric constant than to changes of tan δ. Table III shows some values calculated to show the effect of the dielectric constant on the standing wave ratio in terms of power due to reflections from a perpendicular air–dielectric interface. It is seen that the power standing wave ratio values are very high except for materials having a dielectric constant near 1.0, that is, near the value for air. Most jobs requiring terminations require the power standing wave ratio to be less than 1.5 decibel or less than 1.41 when expressed in simple power ratio. This indicates the necessity for the dielectric constant to be lower than 1.2, whereas we have seen that the materials with satisfactory loss have dielectric constant values 10 to 50 times this. It is therefore necessary in using the lossy materials to alter the geometry of the air–solid interface further in order to reduce the reflections to permissible values. Methods of doing this are discussed under "General Design Features."

Table III. Dependence of the Standing Wave Ratio Due to Reflections From a Perpendicular Air–Dielectric Interface for Low Loss Materials

$$\frac{\lambda}{\epsilon} = 0.7$$

Dielectric Constant	Power Standing Wave Ratio $20 \log \frac{V_{max}}{V_{min}}$ (Db)	$\frac{(V_{max})^2}{(V_{min})}$
1.0	0	1.00
1.2	1.5	1.41
4.0	8.4	6.92
10.0	12.7	18.6
40.0	18.9	77.6

The Dielectric and Thermal Properties of Some Materials Studied

Measurements of several dielectric properties of ceramic and plastic materials were made. One type of material employed has been a ceramic consisting of silicon carbide particles dispersed in porcelain. In Figure 3 is shown plotted the dielectric constant of several of these materials against the frequency in cycles per second.[6] As can be seen the dielectric constant for porcelain is about 6 and practically constant with frequency. For increasing amounts of silicon carbide particles dispersed in the porcelain the dielectric constant increases to as much as 35 to 40. These higher values of dielectric constant evidently are due to Maxwell-Wagner interfacial polarizations resulting from the movement of the conduction electrons in the silicon carbide particles.

In Figure 4 is shown the power factor, which is approximately equal to tan δ in this region, plotted against frequency in cycles per second.[6] The values lie between 0.01 and 0.05 at the lower frequencies but show signs of rapid increase at the highest frequency shown, 60 megacycles, especially for the materials containing the higher percentages of silicon carbide. This is to be expected for such an inhomogeneous material since a maximum loss should occur at some higher frequency, the exact location of the maximum being dependent on the d-c conductivity of the included particles.

Another type of material used quite extensively is a lossy plastic material consisting of graphite particles dispersed in bakelite resin. In Figure 5 one sees that in the case of these materials the dielectric constant as measured at about 3,000 megacycles increases from the low value of about 3 for bakelite to about 70 at 45 per cent graphite by weight. As shown in

Figure 10. Attenuation of half wedge attenuators of graphite plus porcelain as a function of graphite content

Figure 11 (left). Dependence of the attenuation of half wedge attenuators of silicon plus porcelain on silicon content and furnace atmosphere

Figure 12 (right). Dependence of the attenuation of porcelain half wedge attenuators on the wave length

Figure 13. Power standing wave ratio of typical half wedge attenuator as a function of wave length

Figure 6, the tangent of the dielectric loss angle is a somewhat similar function of the graphite content of the attenuator material and reaches a value 1.1 for 45 per cent graphite content. These data show that the loss range for these materials is 0.9 to 219 decibels per wave length.

Another property of the attenuator material which is of considerable importance is the thermal conductivity. For high power applications it is important for the heat to flow readily from the inside to the walls of the wave guide to keep the internal temperatures from being destructive to the material. The generation of heat is greatest where the electric field is highest. Thus in the case of the coaxial conductor where the field builds up logarithmically on approaching the center conductor the heat will be generated most readily near the inner conductor where heat cannot escape so readily as at the outer conductor. In the case of the rectangular guide the electric vector of the dominant wave is perpendicular to the long side of the guide; and has its maximum value along a line perpendicular to the middle of the long edge and drops to zero at the short edges; the heat, therefore, must escape from near the center of the guide to the four faces. In addition to these considerations concerned with the solid in an operating device, in the case of plastic materials it is important in producing strain free moldings that the heat shall flow readily into the material so that curing of the resin is uniform throughout a structure.

Table IV. Effect of Fillers on the Thermal Conductivity of Bakelite

Volume of Filler = 31.7 Per Cent

Filler	Estimated Particle Diameter, Microns	Mean Temp., C	Specific Thermal Conductivity × 10⁴
None		50.0	4.4
Channel black	28	51.2	7.1
Nepheline syenite	2,000–18,000	49.3	9.1
Mica, mineralite 3X	5,000–100,000	46.7	10.6
Silica, fusted	2,000–100,000	48.2	13.5
Acetylene black	43	43.7	14.0
Carbonyl iron	3,000–6,000	43.0	16.5
Copper, lot 2832	500–2,800	50.0	31.2
Copper lot 1598	500–2,800	50.0	46.7
Graphite	2,500–3,000	50.0	104.5

In Table IV are exhibited data showing the effect of various fillers on the thermal conductivity of bakelite. The thermal conductivity is given in the last column. Of the various filler materials measured the graphite filled ones showed by far the highest thermal conductivity. This probably results not only from the high thermal conductivity of graphite but also from its dispersion in the resin and the absence of low conductivity surface films on the granules. One may note that quartz, though a very good electrical insulator, gives an improvement by a factor of about three as compared to pure bakelite molded resin. Though this is a very much lower thermal conductivity than is imparted by the same volume percentage of graphite it was found decidedly advantageous in meeting simultaneously the thermal conductivity, loss, and standing-wave-ratio requirements to employ dispersed silica particles as well as graphite particles in attenuator materials used in high power applications.

General Design Features

Now, as mentioned before, it is necessary in working with these materials to alter the blunt air–solid interface shown in Figure 2a in some manner to reduce the reflections to acceptable values. There are at least two well-known general methods to reduce the reflection of microwaves at air–dielectric interfaces. One of these is to design the end of the dielectric with an approximately quarter wave

Figure 14. Dependence of the temperature coefficient of attenuation of porcelain half wedges as a function of the silicon content and the furnace atmosphere

notch, as shown in Figure 2*b*, such that the reflections from the outside and the inside of the notch are 180 degrees out of phase and therefore interfere destructively. This is satisfactory for narrow frequency applications and is feasible from the point of view of fabrication. For wider band applications, however, it is more satisfactory to employ some type of taper such as is shown in the third illustration, Figure 2*c*. While from the electrical point of view it is best to introduce the taper into the radiation field at its weakest point, that is, at the edge of a rectangular guide or at the outside of a coaxial conductor, other considerations such as mechanical properties of the materials and manufacturing methods may enter in and suggest the advisability of adopting some other way. This is true in the case illustrated in Figure 2*c*; the taper is from one wide face to the opposite one. For such a taper the standing wave ratio oscillates through maxima and minima of gradually decreasing magnitudes, as shown in Figure 7.[7,8] Approximately one to seven wave lengths is the usual choice because of the necessity of reducing the space to a minimum. The restriction on taper length is usually greater in the case of attenuators or terminations for the longer wave lengths due to the larger dimensions of the device.

Experimental Results on Materials and Their Application to Microwave Attenuators and Terminations

Application of Lossy Solids to Attenuator Pads

A variety of specific fixed attenuator pad designs was studied as indicated in Figure 8. Most of these were for rectangular wave guides. Various combinations of ceramic and plastic materials and wave guide and coaxial pads were studied.

Figure 17. Examples of ceramic attenuator

Figure 18. The *BA-461134* "coaxial pad" for the beating oscillator probe

Two of the designs receiving considerable study were the half-wedge type of Figure 8*b* and the *M* type of Figure 8*c*. The first seemed particularly well adapted to the lower attenuation range of 0–20 decibels while the latter was perhaps better for higher values of attenuation.

In Figure 9 are shown curves representing the dependence of the attenuation of *M*-3 pads on the silicon carbide content of porcelain and steatite attenuator materials. As can be seen the attenuation values are lower for the steatite bonded materials. The porcelain materials give

Figure 19. Two ceramic terminations used rather extensively as dummy antennas

Figure 20. Several other ceramic attenuators designed for specific frequency bands

Figure 22. A graphite and bakelite termination developed for absorption of moderate powers

a linear characteristic while the steatite materials give attenuation increasing more rapidly than linearly with silicon carbide content. At the present time we have no adequate explanation of the shape of the curves although they are roughly the sort of things expected.

Some porcelain materials contained added graphite. Figure 10 shows the characteristic obtained for the half-wedge design with increasing content of graphite. The attenuation first increases and then decreases with increasing graphite content. This characteristic is evidently explainable, at least in part, by the conductivity of the material approaching that of a metal with increasing graphite content, thus permitting the wave to go over it with little attenuation since the attenuation for the guide of decreased height is zero so long as the width is maintained constant.

It was found that the characteristic of a ceramic pad not only could be influenced greatly by the bond, the main conductor constituent, and the pad design, but also the temporary binder used for the green ceramic attenuator material. For instance, in Figure 11 it is seen that for a silicon plus porcelain attenuator material fired in a reducing atmosphere the attenuation decreases from 16 decibels to a much lower value with increasing silicon content. The initial high value is due to a small percentage of carbon formed in the porcelain by reduction of the dextrin binder holding the constituents of the unfired ceramic attenuator material together. However, if the firing is carried out in an oxidizing atmosphere the dextrin burns out and quartz films form around each individual silicon particle resulting in d-c specific resistances of the order of 10^{12} to 10^{14} ohm-centimeters instead of 10 to 100 ohm-centimeters obtained in the first case. The resulting characteristic is one that gives increasing attenuation with increasing silicon content.

In Figure 12 is shown the relatively slight dependence of the attenuation on the frequency of the radio-frequency radiation for some of these half-wedge pads. In some cases the results are not this satisfactory but it is of interest that such results are obtainable. Further work is needed to investigate the reproducibility of these results.

In Figure 13 is shown the frequency dependence of the power standing wave ratio of an average ceramic half-wedge. The power standing wave ratio appears to be some periodic function of the frequency, or wavelength as plotted here.

For high power pads it is especially important that the temperature coefficient of attenuation shall be very low, and a pad of very low attenuation to absorb most of the power is often desirable. For this reason the results of Figure 14 on ceramic

half-wedges of silicon plus porcelain are especially interesting. For these materials fired in an oxidizing atmosphere the temperature coefficient for pure porcelain is initially very high, decreases rapidly to zero, and then becomes appreciably negative. For pads fired in a reducing atmosphere the coefficient is initially fairly negative and with increasing silicon content approaches zero.

Pads of varying design were molded from plastic materials. In Figure 15 are shown some results for double half-wedge pads of graphite in bakelite. The lower curve represents the change of attenuation at 25 degrees centigrade with increasing graphite content. For 150 degrees centigrade considerably higher attenuation values are obtained.

In Figure 16 are shown the results for silicon carbide plus bakelite materials as a function of silicon carbide content. The attenuation values are higher the higher the temperature.

Some of the fixed attenuator pads made employing these materials are shown in Figures 17 and 18. The first of these shows several designs utilizing ceramic materials. The second shows a coaxial pad made of a graphite plus phenol formaldehyde material. The latter pad has been used to match a beating oscillator probe into a waveguide.

Application of Lossy Solids to Terminations

As already mentioned, the use of the lossy solids in wave guide or coaxial lines to terminate them and absorb high powers proved to be a most important application. A variety of such terminations were developed in the Laboratories to meet the requirements of specific jobs. In addition to the principles already discussed it was necessary in choosing a combination of design and material to see that unreasonable strains were not created in the material due to too high temperature gradients that might cause physical rupture of the terminations.

Several types of terminations used in microwave equipment and made from the materials already discussed are shown in the following illustrations. In Figure 19 are shown two ceramic terminations that were employed rather extensively as dummy antennae for various 3-centimeter radar systems. The silicon carbide attenuator material represents an improvement over the silicon material in ease and cost of fabrication and stability. In Figure 20 are seen several other ceramic terminations developed for 1-, 6-, and 10-centimeter bands. The larger unit is for 10 centimeters and will dissipate 300 watts average power. Figure 21 shows two coaxial terminations employing two attenuator materials consisting of different relative proportions of graphite, silica, and bakelite. The smaller of the two is shown in longitudinal section. The larger when equipped with a blower and cooling fins will handle a peak power of 750 kw with a duty cycle of about 0.001. Figure 22 shows a graphite and bakelite termination developed for absorption of moderate powers of 1-centimeter waves. One of the uses of this termination is in a directional coupler, the case of which is shown. A typical power standing wave ratio for this termination is 1.03 over the band 24,000 to 25,500 megacycles. Figure 23 shows a molded termination of acetylene black in rubber employed in a 1-centimeter scanner. In this case it was necessary to have a material that would fit snugly in a cavity of complicated shape so as to avoid sparking to the walls.

Application of Film Materials

The second general classification of attenuator materials mentioned was resistor strips. Considerable work was done with sprayed resistor films of graphite pigmented acryloid and graphite pigmented silicone. The first material has been of considerable value as a readily applied lossy material to stop leakage between a metallized radio frequency lens and its enclosing metal horn. The second has been of value in applications where moderate powers of the order of several watts are to be dissipated since the organo-silicon medium will withstand charring at very much higher temperatures than can be tolerated by more conventional organic media. These graphitized silicone films may be employed on ceramic or mica supports. Figure 24 shows such films on mica. These were

Figure 23 (above). A molded termination of acetylene black in rubber employed in a scanner

Figure 24. Graphitized silicone films on mica supports

employed satisfactorily as terminations to absorb powers that quickly destroyed commercially available materials.

Conclusion

In conclusion it can be pointed out that the type of material to be recommended must vary with the particular requirements of the job. Ceramic materials are particularly adapted to high-power and wave-guide applications. Plastic materials are particularly valuable for coaxial usage and certain compositions have served admirably for high power absorption. The plastic materials may be somewhat more suited to quantity production and thin tapers than the ceramic type. However, the best high-power attenuators made so far have been with ceramic materials. Film materials are particularly useful for variable attenuators and also have been widely used in pads and terminations. They are cheap and it is relatively easy to fabricate devices from them. Rubber bonded materials are particularly adapted to those applications requiring the attenuating material to fill a cavity of odd design.

The materials and designs discussed here were developed and produced under the urgent conditions incident to the war. They served the purposes for which they were developed very satisfactorily. Several of the designs were produced in relatively large quantities by outside suppliers working to the Laboratories specifications. At the end of the war the large increase in the demands for units and additional designs had led to the formulation of plans for large scale production of additional designs.

In the future it seems likely that interest in this field will center more on materials and designs for precision jobs with less emphasis on the power handling capacity, which was of prime importance in the present development.

Solutions of the Mathieu Equation

HARRY J. GRAY
NONMEMBER AIEE

RICHARD MERWIN
ASSOCIATE AIEE

J. G. BRAINERD
FELLOW AIEE

IN CIRCUIT THEORY, it is customary, according to one classification, to identify three types of circuits:

(*a*). Linear circuits having constant parameters.

(*b*). Linear circuits having varying parameters.

(*c*). Nonlinear circuits.

Most network theory now existing applies to linear, constant-parameter, circuits (*a*), which are the easiest to handle mathematically and are at the same time the most common ones.

A small amount of work has been done on varying-parameter linear networks (*b*), but for practical purposes the field has not been extensively investigated. Exactly analogous problems have been met in numerous other branches of engineering and physics, and interest has been growing steadily in recent years. The particular purpose of this paper is to present a table of the solutions of an equation which covers one of the simplest cases of a linear circuit containing a varying parameter. The equation has been named by mathematicians the Mathieu Equation, and is given by equation 3. The tables which follow are the first systematic tabulation of solutions to be published. This statement is not meant to apply to tabulations of the periodic solutions. The computation laboratory of the National Bureau of Standards has in preparation extensive tables of these solutions; and previous tables have been published by Stratton, Morse, Chu, and Hutner of the Massachusetts Institute of Technology. W. G. Bickley summarizes work on the Mathieu equation up to 1945[1] and Fletcher, Miller and Rosenhead in their book[2] likewise indicate existing results. These references serve to emphasize the large amount of work done on the periodic solutions, and the lack of work in the nonperiodic solutions, some of which are given in the present paper. It is interesting, however, to note that at least two other agencies were prepared to begin or had begun the computation of similar tables—a commentary on the interest in the results now existing.

The publication of a set of tables of a new function which has application in numerous fields does not have much precedent. Since the present tables represent an analysis of a problem in a little-developed field of electric circuit theory, and since they were obtained by electrical engineers in an electrical engineering institution, it seems reasonable that they should be presented before the AIEE.

An example of a simple varying-parameter circuit might be pictured as a series circuit containing fixed inductance, fixed capacitance, and resistance in series, the resistance being varied periodically or otherwise (the resistor might have an arm connected to a motor or other device, or it might be a carbon-button transmitter the resistance of which is varied by impinging sound waves). The particular varying-parameter circuit of interest here is a simple series circuit containing constant resistance R, constant inductance L, and capacitance C varying in such a way that

$$\frac{1}{C}=\frac{1}{C_o}(1+K\cos\omega\tau)$$

where C_o, ω, and K are constants, $(0<K<1)$, and τ is time. Then i being current,

$$L\frac{di}{d\tau}+Ri+\frac{1+K\cos\omega\tau}{C_o}\int i\,d\tau=0 \qquad (1)$$

This assumes there is no electromotive force in the circuit and that there is some energy stored in the circuit at the time the switch is closed.

Using the instantaneous charge q, equation 1 becomes ($i=dq/d\tau$)

$$L\frac{d^2q}{d\tau^2}+R\frac{dq}{d\tau}+\frac{q}{C_o}(1+K\cos\omega\tau)=0 \qquad (2)$$

By the substitution $q=ye^{-\alpha\tau}$, where $\alpha=R/2L$, the middle term of the equation can be eliminated, and after some slight manipulation, equation 2 reduces to:

$$\frac{d^2y}{dt^2}+\epsilon(1+k\cos t)y=0 \qquad (3)$$

where $\epsilon=(1-R^2C_o/4L)/\omega^2LC_o$ and $k=K/(1-R^2C_o/4L)$, and $t=\omega\tau$. Note that if resistance R can be neglected, $\epsilon=1/\omega^2LC_o$ and $k=K$. Equation 3 is the equation known as Mathieu's equation. As it is the basic equation for the tables which follow, some of the following known characteristics of the equation may be of interest.

Solutions may be stable, periodic, or unstable. A considerable amount of work has been done on the periodic solutions, known as Mathieu functions, because certain physical problems involving equation 3 require that the solution be periodic. This is not the case in the electric circuit problem previously given. An unstable solution is one which ultimately

Figure 1. Stable and unstable regions. Any ϵ, k pair falling in a region between two adjacent curves which start from different points on the $k=0$ axis corresponds to a stable solution, in any other region to an unstable solution, on a curve to a periodic solution

Paper 48-70, recommended by the AIEE basic sciences committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted October 14, 1947; made available for printing December 31, 1947.

J. G. BRAINERD, professor of electrical engineering, RICHARD MERWIN, research associate and HARRY J. GRAY are all connected with the Moore School of Electrical Engineering, University of Pennsylvania, Philadelphia, Pa.

becomes indefinitely large, and this fact has considerable significance physically. However, for small values of t the distinction between stable and unstable solutions may not be evident. In the tables which follow, both stable and unstable solutions occur. Figure 1 shows the values of ϵ and k for which the various types of solutions may be expected.

If, for given values of ϵ and k, a solution y of equation 3 is known for all values of t between 0 and 2π, the value of y for any finite value of t whatsoever can be found.

If, for given values of ϵ and k, two independent solutions of equation 3 are known for all values of t between 0 and π, the solution of equation 3 can be found for any finite value of t. (Different solutions come from different boundary conditions; in the tables that follow, y is called g for the solution which has initial conditions $g=1$ and $g'(=dg/dt)=0$ at $t=0$; and y is called h for the solution which has initial conditions $h=0$ and $h'=1$ at $t=0$.)

Another way of writing the solution of equation 3 is

$$g=u_1 \cos \mu t - u_2 \sin \mu t$$

and

$$H=u_1 \sin \mu t + u_2 \cos \mu t \tag{4}$$

where u_1 and u_2 are *periodic* functions of t with period 2π (u_1 is an even function and u_2 an odd function about $t=\pi$, and about $t=0$), and μ is a constant called the characteristic exponent, which can be calculated from the values of g and h' at $t=\pi$ by

$$\cos 2\pi\mu = 2g(\pi)h'(\pi)-1$$

The quantity H in (4) is directly proportional to $h(t)$:

$$H=H(t)=Mh(t)$$

where M is the constant $[-g(\pi)g'(\pi)/h(\pi)h'(\pi)]^{1/2}$

Equation 4 can also be written:

$$g=U\cos(\mu t+\theta_0)$$

$$H=U\sin(\mu t+\theta_0)$$

where $U=(u_1^2+u_2^2)^{1/2}$ and $\theta_0=\tan^{-1}(u_1/u_2)$. In this form, y could be interpreted as a wave having both amplitude and frequency modulation (Mathieu's equation occurs in high-frequency work in problems such as the analysis of a super-regenerative amplifier).

The relationships between the periodic u functions and the g and H solutions are:

$$u_1=H\sin\mu t+g\cos\mu t$$

$$u_2=H\cos\mu t-g\sin\mu t \tag{5}$$

whence, since the tables give h, g, μ, and M, these periodic quantities can be found.

The tables which follow tabulate solutions of

$$\frac{d^2y}{dt^2}+\epsilon(1+k\cos t)y=0$$

for $\epsilon=1, 2, 3, \ldots, 10$ and $k=0.1, 0.2, 0.3, \ldots, 1.0$. There are thus 100 tables (one for each ϵ, k combination), and in each table are given g and h for $t=0.1, 0.2, 0.3, \ldots, 3.1$ and for $t=\pi$. The g and h are the solutions of equation 3 for the boundary conditions $g(0)=1$, $g'(0)=0$, and $h(0)=0$, $h'(0)=1$. In addition to g and h, there are given in a separate table the values of μ and M. The tables are given to five decimal places, but because they are extracted from larger ones and no rounding has been done, the digit in the fifth decimal place may be in error, and it seems best to state the accuracy of the tables as four decimal places. In this connection, it may be pointed out that the tables were obtained on the electronic numerical integrator and calculator (ENIAC), using 10-digit numbers and an interval $\Delta t=0.0004$ in the corresponding difference equation. Rounding and truncation errors cut the accuracy so that 5 or 6 figure accuracy might be expected.

During the ENIAC runs, the quantity $gh'-hg'$, which should equal 1 for all values of t, was automatically computed and noted. Any run in which $gh'-hg'$ was out more than 1 in the seventh decimal place was rerun. The computation laboratory of the National Bureau of Standards (Dr. Arnold N. Lowan, Chief) checked by hand several values in the tables, showing agreement to 5 or 6 decimal places. No further checking has been done. To find values of g and h for values of t not given in the tables, calculate u_1 and u_2 by equation 5, and use the expressions for g and H in terms of u_1 and u_2, and μ as previously given.

If it is desired to find a solution of equation 3 when the right-hand side is not zero (this would be the case if an electromotive force were in the circuit), use may be made of the fact that when two independent solutions (such as g and h) of the homogeneous equation 3 [3 is homogeneous] are known, the solution of the non-homogeneous equation [right-hand side not zero in equation 3] can be found. See for example Ince.[3] Equation 19 of reference[4] which can be shown to be Mathieu's equation with right-hand side not zero.

As a matter of interest, it may be noted that in construction of the tables, the ENIAC carried out approximately the equivalent of 7,500,000 multiplications of two 10-digit numbers, and a considerably greater number of additions and subtractions, in a total time of 12 hours. Tables of g' and h' were formed at the same time g and h were tabulated, and although the former (g' and h') are not given here they can be supplied. In the reference to Ince in the preceding paragraph, it may appear that g' and h' are needed, but the fact that $gh'-hg'=1$ for each value of t eliminates this requirement and simplifies greatly the obtaining of a solution when the right-hand side of equation 3 is not zero.

Insulation Breakdown as a Function of Area

L. R. HILL
MEMBER AIEE

P. L. SCHMIDT
ASSOCIATE AIEE

THE COMMERCIAL USE of insulation involves many complicated problems, one of which concerns the manner in which the distribution of breakdown strength changes with increasing area of insulation under test. Limited test data[1] indicates that the probability of failure at a low voltage increases as the area under test is increased. This theoretical problem was discussed in general terms by F. W. Peek[2] and in some detail by M. C. Holmes in two previous publications,[3,4] but the actual distribution of breakdown voltage was not obtained.

It is the purpose of the following discussion to obtain theoretically the distribution of breakdown voltages of large areas of insulation from the voltage breakdown distribution of small areas based on the variability of breakdown voltage from one small area to another. Electrode edge effects and poor contact effects, discussed elsewhere,[5] are neglected since this paper does not attempt to encompass a complete theory of dielectric breakdown nor to correlate the theory developed with published breakdown data[6] which, in general, are not statistically critical and include effects other than nonuniformity.

Insulation uniformity is most easily studied by statistical methods[7,8] which are briefly reviewed in the following paragraphs for those who do not make frequent use of this tool.

A series of insulation tests on samples taken from the same basic material will be distributed about an average value in an approximately normal manner; that is, the average value will occur most frequently and values on each side of the average will become decreasingly numerous, according to a definite law called the normal law. The probability of breakdown at any given voltage is the ratio of the number of samples failing at that voltage to the total number of tests. The standard deviation of a normal distribution is the numerical value which, when added to and subtracted from the average value, forms a set of limits which will include 68 per cent of the values in the distribution. When the insulation under test has a high variability, the ratio of the standard deviation to the average value is large, while insulation having good uniformity will give a distribution which has a small ratio of standard deviation to the average value. Typical values of the ratio of standard deviation to average value expressed in per cent for a few common insulating materials are given:

	Per Cent
Air	1– 2
Oil	4– 8
Paper	6–15
Laminated Mica	10–40

Distributions are said to be continuous if all values are possible and discontinuous if only discrete values are obtained. Usually continuous distributions are represented by curves and discontinuous distributions by histograms such that the area under the curve between any two values is proportional to the relative frequency of occurrence of values within that range. The familiar bell-shaped normal distribution curve is obtained in this manner. A more convenient way of studying normal distributions is to plot cumulative per cent of values at and below a given value against that value on a special type of graph paper called probability paper. This paper is so designed that a set of observations which are normally distributed form a straight line when plotted cumulatively since the scale on one of the co-ordinates is spaced in accordance with the normal law. The average value of a distribution which is represented by a straight line on this paper is that value where the line intersects the 50 cumulative per cent line, and the standard deviation is the difference between the average value and that value where the curve intersects the 16 or 84 cumulative per cent line.

It should be remembered that this useful normal law is a special case of the more fundamental binomial law which enables one to calculate the probability of occurrence of an event when certain specialized conditions are fulfilled. The binomial expression is perfectly general and makes no assumption concerning the form of the basic distribution involved.

We will show that theoretical cumulative probability of breakdown for n elemental areas in parallel is related to the cumulative probability of breakdown for an elemental area by the expression:

$$\text{Cum } P_{BD_n} = 1-(1-\text{cum } p)^n \qquad (1)$$

where

cum P_{BD_n}

is the cumulative probability of breakdown at R volts for n elemental areas in parallel and cum p is cumulative probability of breakdown for one elemental area at R volts.

Also, in those cases where discontinuous distributions are involved, the theoretical probability of breakdown at any given voltage is given by:

$$P_{BD_n} = \left[1-\left(1-\sum p_e[1,2,3,\ldots.i]\right)^n - \left(\sum p_e[1,2,3,\ldots.(i-1)]\right)\right] \qquad (2)$$

where

P_{BD_n}

is the probability of breakdown at R volts for n elemental areas in parallel, P_e is

Paper 48-69, recommended by the AIEE basic sciences committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 5, 1947; made available for printing December 24, 1947.

L. R. Hill is assistant manager, materials engineering department, and P. L. Schmidt is with the magnetic group of the same department, Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 2. Voltage breakdown distributions for partial and multiple areas of an elemental area ($n=1$) when the distribution for the elemental area has an average value of ten units and a standard deviation of one unit

the probability of breakdown at voltages up to and including R volts for an elemental area and p_c is the probability of breakdown at voltages up to but not including R volts for n areas in parallel.

Tables giving theoretical expected breakdown voltage, normal distribution curves and typical examples for parallel area breakdown are included.

Theory

How can one determine the theoretical manner in which a breakdown distribution should change when n elemental areas are tested in parallel?

Given a distribution of breakdown values, all of which have associated with them a finite frequency of occurrence, the reasoning by which we arrive at the solution is as follows:

A. It is possible to obtain the probability of exactly *no* breakdown at any voltage by using the binomial expression

$$P_n(O) = C_o^n p^o (1-p)^{n-o} = (1-p)^n$$

where p is original probability of breakdown at the desired voltage for an elemental area. See Symbolism and Definitions of Terms.

B. This value, when subtracted from one might be expected to give the probability of at least one breakdown out of n samples or areas at the chosen voltage. However, this does not specifically exclude lower voltages on the remaining areas, which case would constitute a breakdown at a value below the desired voltage.

C. In order to exclude specifically lower voltages than that desired, it is necessary to use the cumulative frequency from the lowest value to and including the desired value as that value of p in the expression under A.

D. The expression

$$P_n(O) = C_o^n \left[\sum p[1,2,3,\ldots.i]\right]^o \times \left[1-\sum p[1,2,3,\ldots.i]\right]^{n-o}$$

$$= \left[1-\sum p[1,2,3,\ldots.i]\right]^n$$ then gives the probability of obtaining exactly *no* breakdown at or below the desired voltage.

E. Now if the value $P_n(O)$ is subtracted from one, we obtain the probability of at least one breakdown at or below the desired value, or in other words

$$\text{Cum } P_{BD_n} = 1-(1-\text{cum } p)^n \qquad (1)$$

F. However, if discontinuous distributions are involved, it is necessary to subtract not only $P_n(O)$ from one, but to also subtract the P_{BD_n} values for the $1,2,3,\ldots.(i-1)$th terms in the distribution. These P_{BD_n} values will be called the corrected probability values and will be represented by $P_c(1)$, $p_c(2)$, and so forth.

G. The probability of breakdown at any voltage when n elemental areas are under test then becomes:

$$P_{BD_n}\left[1-\left(1-\sum p_c[1,2,3,\ldots.i]\right)^n - \left(\sum p_c[1,2,3,\ldots.(i-1)]\right)\right] \qquad (2)$$

Application

In order that equation 1 may be easily used as an engineering tool, values of cumulative probability for several values of n times the original area under test are given in Tables I and II.

These theoretical probabilities of voltage breakdown for n elemental areas are not restricted by the shape of the original breakdown distributions but are applicable to any distribution.

It should be observed that the testing of several areas in parallel tends to shift the peak or most probable value of the distribution toward the lowest breakdown value. Distributions which are originally approximately normal, remain approximately normal but actually tend to skew somewhat. The extent of this distortion is less than the usual experimental error for determining the original breakdown distribution, but is of considerable theoretical interest. Since any area subject to dielectric breakdown can be considered to be made up of smaller elemental areas, the weakest of which determines the breakdown of the sample, it is obvious that actual breakdown distributions cannot be normal. Considering that the original distribution for an elemental area is normal, the divergence from normality for 1/2, 2 and 100 elemental areas is shown in Figure 1.

A useful plot, using a normal cumulative curve as the original distribution which has a standard deviation of one and a median value of ten, is shown in Figure 2. Cumulative probability curves for breakdown where 0.01, 0.1, 0.25, 0.5, 1, 2, 4, 10, 100 and 1,000 elemental areas are in

0.9934	0.92	0.72	0.39	0.05	0.005

parallel are given. Although the curves are approximations, they do not greatly deviate from normality and have been found to represent manufacturing experience fairly well.

These curves can be used to represent any set of data by simply placing an auxiliary scale along the abscissa. This auxiliary scale should be so constructed that the median value for the data represented corresponds to ten on the original scale. The standard deviation for the data should be represented on the new scale as a distance equal to one unit on the original scale.

For example, consider a voltage breakdown distribution having a median value of 4,500 volts and a standard deviation of 650 volts. The median value, 4,500 volts, will be placed at ten on the original scale, nine on the original scale now becomes 3,850 (4,500−650) and eleven on the original scale becomes 5,150 (4,500+650) and so forth. In this particular case, the median value for 100 elemental areas in parallel is found to be 2,875 volts and the standard deviation is 250 volts, using the curve for $n=100$, Figure 2.

It should be emphasized that the ratio of standard deviation to median value becomes smaller, although both decrease, with increasing number of parallel units. It is obvious that a small initial value of standard deviation is, in many cases, more desirable than a high median value. The value of standard deviation determines the rate at which the median decreases! It can be seen from this that high variability may be the source of severe manufacturing and field difficulties in the application of insulating materials.

Discussion

The practical application of insulation may involve areas much greater than the usual area of samples tested in the laboratory. Practical experience has shown that these large areas will fail at voltages below the sample test voltage, and a necessary factor of safety has been established empirically for many applications. Thus, when a certain lower limit of breakdown voltage is required for practical applications, the insulation must be such that the average and dispersion of laboratory tests indicates a much higher breakdown voltage.

The theoretical solution to this problem shows why the use of an empirical safety factor is necessary since the breakdown distribution for multiple areas shifts towards the lowest value in the original sample distribution.

Improvements in variability in basic insulation quality have allowed reduction of the safety factor on many occasions. Such basic quality changes can now be evaluated by testing small samples in the laboratory and predictions concerning insulation performance can be made through the application of the foregoing theory when the relative areas are known.

Symbolism and Definition of Terms

Cum P_{BD_n} = probability of breakdown for n elemental areas at and below a given voltage

cum p = probability of breakdown for an elemental area at and below a given voltage

P_e = probability of breakdown for an elemental area at any discrete voltage

P_c = probability of breakdown for n elemental areas in parallel at any discrete voltage; also called the corrected probability of breakdown for n elemental areas at a given voltage

R = discrete breakdown voltage

n = number of elemental areas tested in parallel

$P_n(m)$ = probability of m successes in n trials

$P_n(O)$ = probability of *no* successes in n trials

C_m^n = number of combinations of n things taken m at a time

Discussion

Hamilton Brooks (Westinghouse Electric Corporation, East Pittsburgh, Pa.): Hill and Schmidt have made a useful contribution by reducing a complicated mathematical relation to a simple set of easily read curves. Modern statistical mathematics can be a powerful engineering tool, but many statistical processes are laborious or appear formidable from a mathematical point of view and many engineers are often discouraged from applying them to every day problems. There is a real need, therefore, for development in engineering applications of statistics. We have found statistical theory valuable in analyzing and predicting the performance of capacitors made with impregnated paper insulation and are fortunate in having a large amount of experimental data to substantiate such relations as derived by the present authors.

A relation of great practical significance is that dielectric strength varies as the logarithm of the area. In effect, this means that one may test samples of two different

Figure 1. Distribution of breakdown voltage for number 30 enameled wire

Curve A—Samples six inches long
Curve B—Samples twenty-four inches long

Figure 2. Additional data on same wire as shown in Figure 1

Figure 3. Curves showing the effect of variability on the breakdown distributions as the area is increased

areas and plot the voltage at which breakdown most frequently occurs against area on semilog paper. A straight line between the two points can then be projected to show the most probable strength of areas 100 or 1,000 times as large. This, of course, is not valid if we materially alter conditions in going to increased areas.

In assuming a simple normal distribution as a basis for their curves, the authors introduce certain errors, which they recognize but point out may be tolerated in attaining the desired simplicity. It should not be overlooked, however, that an important use of statistical analysis is in isolating and evaluating causes of variability. In this connection, it has been found worth considerable effort to rigorously derive the distribution of certain types of flaws in paper and calculate the resulting sampling distribution of defects in finished capacitors. It has been possible to obtain valuable improvements in insulating paper once the importance of particular kinds of imperfections was understood.

Benjamin Epstein (Carnegie Institute of Technology, Pittsburgh, Pa.): It may be of interest to point out that the problems considered in the paper are similar to those which occur in many different branches of science. The important thing from the physical point of view is whether or not we are dealing essentially with a "weakest link" situation. If such is the case then we have the key needed to find the relationship between the strength of specimens and their size. The term strength in this connection may be quite general in scope. We may have in mind mechanical strength, electrical strength, resistance of painted specimens to the corrosive effects of the atmosphere, or perhaps the life span of a device which ceases to function when any one of a number of vital parts breaks down. From a statistical point of view such phenomena, though different at first glance, are really equivalent since they lead in each instance to the same problem, namely the distribution of largest or smallest values in large samples. It turns out that the investigations by mathematical statisticians concerning the distribution of extreme values renders it possible for the engineer to make quantitative and not merely qualitative statements about size effects. The ability to make numerical estimates may be of considerable importance to design engineers. The role of the theory of extreme values in fracture phenomena is considered in a recent paper by the discussant.[1]

REFERENCE

1. STATISTICAL ASPECTS OF FRACTURE PROBLEMS, **Benjamin Epstein.** *Journal of Applied Physics* (New York, N. Y.) *19*, 1948, pages 140–7.

L. R. Hill, P. L. Schmidt: The authors feel that the discussions submitted by Epstein and Brooks bring out two important points which should be re-emphasized. First, that the scope of the statistical theory presented is not confined to the study of insulation breakdown as a function of area, but is applicable to all problems which involve the failure of a material due to the failure of its "weakest link." In all cases the average strength and variability decrease as the area increases. Second, that the theoretical treatment presented is in agreement with a large amount of engineering data on capacitor paper performance.

The authors have also found agreement between the theoretical and actual change in the distribution of breakdown voltages for enameled copper wire as the area under test is increased. Samples of wire six and twenty-four inches long, respectively, were submerged in a mercury bath and an increasing voltage was applied between the mercury and the copper. The voltage at which breakdown occurred for thirty samples of

each length was observed and the distributions obtained are shown on the accompanying curves. Figure 1 gives the distributions for six-inch lengths, Curve A, and twenty-four inch lengths Curve B taken consecutively from a spool of number 30 wire, and Figure 2 shows the data obtained from a different section of wire from the same spool.

The broken lines, which envelope the distribution curves on Figure 3, represent the 0.95 confidence limits of the distributions, or, in other words, the chance is 19 to 1 that the error in the average and standard deviation due to the finite sample size is not greater than that amount which would cause the curves to fall outside their respective envelopes.

It can be seen that the breakdown distributions for six-inch lengths are significantly different from the distributions for the twenty-four inch lengths. The average value for the twenty-four inch long samples, predicted by theory from the distribution for the six inch samples, is within approximately five per cent or less of the actual average value obtained by test, and the true and predicted standard deviations agree to within approximately ten per cent or less.

It should also be emphasized that the standard deviation determines the rate at which the average value decreases as the area increases. In Figure 3 the solid curve, indicated as $n=1$, has a higher average value and a greater standard deviation (variability) than the broken curve. However, as the area is increased 1,000 times ($n=1{,}000$), the broken curve has a higher average than the solid curve. It can be easily seen from this example that an insulation which has a high average value and a large variability on laboratory tests may not be as satisfactory in an application involving large areas as an insulation which has a lower average but a smaller variability on laboratory tests.

Introduction*

COMPRESSION-TYPE cable for high-voltage transmission has been used in England and on the Continent since 1932 and experimental work on this type of cable in the United States was reported on in 1939. In 1932 an experimental installation was made in the United States of an Oilostatic system, followed in 1934 by a commercial installation.

In the compression-cable system used in England and on the Continent a lead sheath on each of the single-conductor cables served as a flexible membrane for transmitting pressure to the cable insulation. The use of a lead sheath entailed two disadvantages for high voltage single conductor cables, namely, increased losses due to sheath currents and possible rupture of the lead sheath under repeated load cycles. In the usual high-pressure oil-type pipe systems and some high-pressure gas systems the lead sheath is removed prior to installation in the pipe, thereby subjecting the nonjacketed cable to contact with the atmosphere during installation and to contact with the inside of the pipe or its internal coating and the oil in the pipe.

The elimination of the lead sheath with its inherent disadvantages, on compression cable and the possibility of installing some type of jacketed cable in the field appealed to the companies whose representatives are presenting this paper.

During the early part of 1946 it was decided to install a tie line between the systems of the Consolidated Edison Company of New York, Inc., and the Long Island Lighting Company. A study of the tie requirements revealed that 138,000 volts was the economical voltage to be used for a line which would be required to transmit 75 megawatts between the two systems. For some time prior to this decision by the operating companies, the engineers of the Phelps Dodge Copper Products Corporation had been conducting extensive tests on a compression-type cable and presented data to the operating companies to aid them in making a decision regarding the type of circuit to be installed.

In order to further the development of high-pressure pipe-type cables and to obtain the advantages mentioned before, agreement was reached to install a polyethylene-sheathed compression cable. In making this decision the economic aspect was given full consideration.

In the following sections the manufacturer and the users are presenting a complete description of all the phases of work involved in the design, manufacture and installation of this newest type, high voltage, pipe cable.

The Compression Cable: Its Evolution and Basic Characteristics*

History

European Installations

The effectiveness of keeping oil-paper insulation at all times filled with oil under pressure in order to suppress ionization and failure was brilliantly demonstrated by Luigi Emanueli in his researches, commencing about 1923, and culminating in 1927 in extensive installations of the Pirelli oil-filled cable in New York and Chicago at 138,000 volts. This achievement was emphasized by the background of operating failures of paper cables at only 33 kv and less which most countries were then experiencing. But although twenty years of operating experience have established the principle of maintaining the impregnating oil under pressure, accessories of the oil-filled cable system are numerous, and may require much servicing.

In late 1926 Martin Hochstadter commenced research in London at the Enfield Cable Works, Ltd. to find a simpler and more economical way of making high-voltage cable. Departing from Emanueli's principle, he applied radial pressure to the insulation through a diaphragm. First, he tried pressure on the insulation from the conductor outward. Propagation of pressure across the dielectric from the inside out, however, is incomplete. He then tried applying pressure from the outside in—that is, an ordinary cable with lead sheath was subjected to external pressure. At 200 pounds per square inch ionization was effectively suppressed. But after only a few load cycles the lead sheath would stretch, fold over, and crack. The final solution came in making the cable out-of-round in cross-section, and in reinforcing

* J. E. McCormack.

* K. S. Wyatt.

the lead sheath with thin bronze tapes, so that its periphery was fixed in length. These features enabled the sheath to expand and contract in volume content, with varying load, without being stretched and folded. It was then found that cables with 66 kv insulation could be rated at 132 kv and tested at 228 kv on load cycles to 90 degrees centigrade with complete freedom from ionization and breakdown. Other accelerated tests in a nonoxidizing pressure medium showed the reinforced lead sheath should perform satisfactorily for 50 years or more. The new system was called The Pressure Cable and was described before the Royal Society of Arts by Hochstadter, Vogel and Bowden, in December 1931.[1]

The first commercial pressure cable, $2^1/_2$ miles long, was installed in London in 1932.[2] A 3-core cable, impregnated with rosin compound and insulated with 33 kv solid cable thickness, with a triangular lead sheath over-all (*HSO*), was pulled into a steel pipe and operated under 200 pounds nitrogen pressure at 66 kv. This cable has operated satisfactorily ever since without incident, even though during the German blitz of 1940–41 a bomb displaced and dented the pipe, and even though other nearby cables, some at 66 kv all failed. However, the original corrosion protection was inadequate and the pipe later had to be recoated.

An experimental installation for a type test of 66 kv pressure cable was made at Wood Lane, London, by Callender's Cable and Construction Company in early 1933. After three years' testing under load cycle at over-voltages, Dr. D. M. Robinson pronounced the system completely satisfactory, except for some corrosion of the steel pipe, which again had been inadequately protected.

Another experimental installation 110 yards in length and at 260 kv was made at the KEMA Laboratories in Arnheim, Holland, in 1936. The maximum stress employed was nearly 400 volts per mil. The cable was loaded to 90–95 degrees centigrade copper. During installation air got into the cable at a joint and caused oxidation and copper soap formation, and this finally resulted in a failure near the joint. A second cable was made to replace the first in which a larger copper was used so as to limit maximum temperature on the load cycle to a reasonable value, but the insulation thickness was still further reduced to give a maximum stress of 425 volts per mil. Aside from terminal trouble, the cable operated satisfactorily for 250 load cycles. Since solid cables operate at maximum stress of 70 volts per mil and oil-filled cable at 245 volts per mil, the foregoing test at 425 volts per mil was regarded as an achievement.

After the London cable installation had operated successfully for two years, an increasing number of pressure cables in steel pipe were installed in Europe. Copenhagen, Denmark, and Oslo, Norway, were among the first. By then the German authorities realized the ruggedness of the steel pipe construction under aerial warfare, and installations followed at Muldenstein, Stettin, Brunswick, Barmen, Elberfeld, Munich, Watenstett, and Magdeburg, until by 1940 there were 14 installations in all.

During the war, the pace was accelerated and despite the acute shortage of steel, other pipe installations went in at Gottingen, Zschornewitz, Reichswerke, Berlin, Dessau, Finkenheerd, Heidebruck, Hamburg, and Salzburg, bringing the total to 24, of which nine were at 100 kv or over. Noteworthy is the tendency to repeat, where a pipe cable has once been laid; for example, the installations at Brunswick and Elberfeld were each followed by two others, and that at Munich by a second.

In England, however, there was prejudice against the steel pipe because of corrosion troubles. When the pipe was replaced with a reinforced lead sheath applied over the cable at the factory, the self-contained Pressure Cable, as it was called, found immediate acceptance.[3] Installations were made in 1940 and 1941 at London, Ferrybridge, Rotherham and Doncaster, all at 66 kv. Since the war other installations have gone in, one at 132 kv at Osbaldwick, Yorkshire, two at Newcastle, and one at Sidney, making a total of eight self-contained compression cables. A short length is operating experimentally at 264 kv.

All in all, there are now 32 installations of the pressure cable abroad, all operating satisfactorily, with the exception of one or two in Europe damaged by bombs. This high-tension cable system is therefore second in operating mileage and experience to oil-filled cable. There has been one failure, and this occurred on the Copenhagen line next to a joint as a result of differential expansion of the steel armoring and the lead sheath, at a point where the armor was improperly anchored at a joint. This trouble necessitated replacement of a considerable length of cable. Some corrosion of the steel pipe was encountered at Oslo, but was corrected at an early date by cathodic protection. One of these lines runs in mountainous areas for thousands of feet down 25 per cent grades. Several installations have appreciable vertical risers at terminal ends, one to a height of 80 feet. With the exceptions noted, operation has been satisfactory and maintenance negligible.

These European installations all employed nitrogen gas as the pressure medium. The pressure was maintained at 200 pounds per square inch. The compressed gas acted upon the reinforced lead cable sheath but did not make direct contact with the oil-paper insulation. However, oil was sometimes used as the compression medium in the single-core tails which were housed in copper tubes leading to the terminals at either end. Such oil was separated from the insulation by the lead sheath as was the gas. In the 1932 London line, for example, both oil and gas were employed as the compression medium; since the tails were only 50 feet long, only 300 feet of cable were compressed with oil. Gas was preferred because it did not involve complicated expansion reservoirs and semi-stop joints, and because pressure is uniform from end to end of the line irrespective of profile and of load variation. In the experimental work, a sheath of oval form was used for single-core cable, and of triangular form for 3-conductor cables. About 1936 the single-core oval cable with each core separately sheathed (*HSL*) became the accepted practice. Because the cable was protected by a sheath, none of the steel pipe lines was cleaned or coated inside.

It was not long after the initial success of the pressure cable before other cable systems in steel pipes or in reinforced lead sheath filled with oil or gas at 200 pounds per square inch began to appear. They had only one major point of difference, namely, the oil or gas pressure medium was not separated by a sheath, but was in direct contact with the insulation. Many of these systems were called pressure cables. In order to distinguish the original system from these newcomers, the name, the pressure cable, was changed to the compression cable. The term "compression" brings out very aptly the essential point of difference between the systems. In the compression cable the pressure medium acts on the cable sheath, and the latter in turn acts on the insulation, compressing it layer against layer with a positive piston action; whereas in the cable systems without sheath the pressure medium merely runs in and out of the insulation by means of the interlayer path as the pressure fluctuates. Of course, the sheath is quite useful also for protecting the insulation against moisture or other contamination, and in the case of

gas-filled pipe it prevents the oil ratchetting out of the insulation on slopes or vertical risers.

Simplification of Design

Although successful abroad, steel pipe cables at extra high voltage found no general acceptance in this country until recently, partly because of limited plant expansion in the 1930's, partly because the economics of pipe systems had not been demonstrated, and because utility engineers were concerned over the methods of protecting the steel pipe against corrosion. The clumsy and expensive European compression cable design with its steel-armored cable and complicated joints further contributed to this lack of interest.

It should be noted that in 1934 the Pennsylvania Railroad installed a 132-kv Oilostatic cable in a steel pipe. The system proved entirely satisfactory except for some corrosion trouble, but it was not until 1940 that a second extra-high voltage installation was made at Burlington, New Jersey, at 138 kv.

The first step in simplification was taken in 1940 by L. I. Komives in an experimental field installation of compression cable at 120 kv at Detroit.[4] He dispensed with the steel armor, bedding and binder tape around the three *HSL* cores, and used a simple solid-type joint. The three cores were still triplexed, however. The pipe was filled with nitrogen at 200 pounds per square inch. The results of several years of loading tests showed complete stability even though the lead sheath of one core had been purposely punched with holes at 25-foot intervals. When a commercial seven mile line of 120-kv cable was installed at Detroit in 1941, the compression cable design was not selected, but instead a cable without sheath in a steel pipe filled with 200 pounds per square inch nitrogen. In this cable the three single cores were not triplexed, it being impossible to strip the lead from the single cores of a triplexed cable.

The reason for the non-selection of the compression cable lay not in its electrical characteristics, which are superior to those of most other types, but in its economics as then designed. The great weight of the lead sheath in the triplexed design made for only 800 feet pulling lengths as against 2,000 feet for cables not triplexed and with sheath stripped off. This more than doubled the number of joints and manholes. In addition, with large conductor sizes such as are usually used in this country, appreciable losses occur in the lead sheath which would sometimes necessitate a larger size conductor. The energy losses in the sheath also represent an appreciable annual charge. Above all, utility engineers, as a result of long experience, did not trust lead.

The European compression cable design was clearly uneconomic for our conditions, and at this time serious thought was given to the development of another type of steel pipe cable without sheath. But with the knowledge of the actual conditions of installation in the field, the effects of accidental rust, mud, asphalt and moisture on the unprotected insulation in the pipe, the difficulties of pulling an unsheathed cable during long periods of rainy weather or high humidity, and tedious treating of each section of cable during installation, it became more and more apparent that a manufacturing operation that ought to be done in the factory would have to be done in the field under conditions difficult to control. Not only were these conditions a hazard to the life of the cable, but they might greatly increase the over-all cost of an installation in spite of the cable itself being cheaper. In those cases where the pipe was filled with gas, the factor of safety (long-time breakdown voltage to operating voltage) dropped to half or less. Even traces of moisture in the nitrogen gas at the feed point would in time weaken the insulation at such a location. On slopes or vertical risers the oil would ratchet out and drain from the insulation. If the pressure were lost, the cable would immediately have to be taken out of service. And finally, an oil-filled terminal could no longer be used even if a stop gland were employed at the terminal base, as the oil would run through the insulation and out into the pipe, necessitating a gas-filled terminal of inferior electrical strength.

The European compression cable therefore was examined once again with a view to further simplification. In addition to the improvements due to Komives, it was decided to replace the heavy lead sheath with a plastic sheath. After a search of available materials, and after experimental work with the more promising, polyethylene was selected. Three lengths of 132-kv cable were sheathed with this light-weight, tough and elastic material, using a 63-mil wall. The plastic sheath was then reinforced with two 5-mil bronze tapes. After a series of tests, to be described in another section of this paper, the new reinforced polyethylene sheath was found to be a solution of the problem.

In order to increase pulling lengths and reduce the number of manholes and joints, two further steps were taken. Over each core three *D*-shaped copper skid wires were applied with a lay of 12 inches, as compared with the 2-wire 3-inch lay which had been used heretofore. Then triplexing was abandoned, and it was decided to pull into the pipe three single-core cables, each from a separate reel.

No difficulties have been experienced from bends as it has been possible to keep the radius in all cases, except at terminals, to at least 33 feet. European cities, with their narrower and more crooked streets, have required bends of 6 feet radius, and these have caused no trouble with the size cables used.

The replacement of the lead sheath with a polyethylene sheath in many cases about halved the weight of the cable, making it possible to pull 2,000 feet instead of 800 to 1,000. The long lay skid wires reduced the coefficient of friction from 0.39 to 0.23, still further increasing the possible pulling length from 2,000 feet to 3,000 feet.

The Plastic-Sheathed Compression Cable

The new construction as used on the New York–Long Island Line is as follows: Three impregnated paper-insulated copper conductors with bronze reinforced plastic sheath are pulled into a steel pipeline laid under the streets. The pipe is filled with oil at 200 pounds per square inch.

An oil of 3,000–4,000 Saybolt universal seconds at 100 degrees Fahrenheit is used to impregnate the insulation. This viscosity gives maximum electrical and chemical stability consistent with mass-impregnation methods. Where oil is used in the pipe as the compression medium, the mobility requirements of the system dictate the use of a low-viscosity oil, around 700 Saybolt universal seconds at 100 degrees Fahrenheit. Thus, owing to the presence of the sheath it is possible to use a high-viscosity oil in the insulation such as will give stable electrical characteristics, and a comparatively low-viscosity oil as the pressure medium such as will give good low-temperature flow characteristics.

The pipe is protected against corrosion by 1/2-inch thick extruded asphaltic coating. The adoption of an extruded pipe coating has met the objections to steel pipe which interfered with the early adoption of this system. The installation of 7 miles of pipe cable at Detroit has demonstrated the effectiveness of this type of protection by five years of service.

Joints are essentially a carefully made solid joint, the hand applied insulation consisting of oil-impregnated paper tape, covered with polyethylene tape. They

Figure 1 (left). Effect of applying pressure to a 3-core 66-kv solid cable exhibiting serious ionization as a result of overheating

1—before, 2—after application of 12 atmospheres pressure external to the lead sheath for five hours

Figure 2. Single core 66-kv HSL 380,000 circular mils subsequent to overheating and draining

are described in detail in another section of this paper. Semistop joints, excepting at terminal ends, are not required on the compression cable system, since treating and filling of the entire line is carried out in one operation.

The compression cable itself, apart from the compression medium, requires no expansion reservoirs, as it is automatically self-compensating. The oil pressure medium requires an expansion reservoir with pumps installed at one end or both ends of the line.

Terminals are of the standard oil-filled type with an inner tube carrying the high pressure. A small compensator is mounted on each terminal which by means of a flexible membrane separates the oil pressure medium in the pipe from the oil in the cable, and at the same time communicates the pressure in the pipe to the oil in the terminal. A gland or stop at the base of the porcelain prevents the oil in the terminal from draining into the pipe. There is no appreciable pressure drop across this gland because the compensator maintains a balanced pressure on each side.

Basic Characteristics

Effect of Pressure

The application of 180 pounds per square inch pressure to a solid lead-sheathed cable exhibiting serious ionization is shown in Figure 1. After a few hours ionization has completely disappeared. Even when a cable is practically "dry" or free from compound, pressure external to the lead sheath will suppress ionization, albeit more slowly than with a good cable, Figure 2. Curve *A* represents ionization after draining, and curve *B* shows the absence of ionization after the application of 200 pounds per square inch for seven hours. Curve *C* shows that the effect of pressure is persistent long after it has been removed; even then at operating voltage there is no discernible ionization.

Ionization is so completely eliminated by high pressure external to the sheath that the maximum dielectric strength inherent in oil-impregnated paper is realized. Using the time-voltage test as a criterion, a solid cable reaches a breakdown value of about 400 volts per mil maximum stress for indefinitely long application of voltage, Curve *A*, Figure 3. If 200 pounds per square inch are applied external to the sheath, an asymptotic value of 1,000 volts per mil or higher is attained even without strand shielding, curve *B*. Thus the factor of safety (long-time breakdown strength/operating voltage) in a compression cable is four times or more. Owing to the sheath keeping the insulation filled with oil, and protecting the insulation from contamination, this factor of safety represents, not merely an initial value, but a value permanent throughout life.

The compression effect is operative under severe and prolonged load cycles. For example, a 132-kv cable was given 105 load cycles under 200 pounds per square inch to conductor temperatures of 80 to 93 degrees centigrade at a maximum stress of 375 volts per mil. The test occupied over a year, during which the cable was continuously under voltage. Ionization was completely absent both before and after test. The only change was improvement of the base power factor, probably due to minute pores in the paper becoming filled with oil, Figure 4.

On a lead-sheathed compression cable, as normally made, the critical pressure at which ionization disappears, when pressure is first applied, is 90 to 100 pounds per square inch. For a polyethylene-sheathed cable the critical pressure is lower, between 50 and 70 pounds per square inch. A pressure of 200 pounds per square inch has been standardized for normal operations so as to give a suitable margin of safety.

Since pressure completely suppresses ionization, breakdown occurs, if the voltage be raised sufficiently high, not by the usual tracking or dendritic mechanism, but by a straight-through puncture.

Propagation of Pressure

The compression cable is made oval in cross-section for two reasons, to accommodate oil expansion, and to make the insulation responsive to the applied external pressure. When the cable is loaded and heats, the insulation expands

slightly on its minor axis and contracts correspondingly on its major axis, that is to say, the oval cross-section becomes more nearly circular. When load is removed and the cable cools, the external pressure acting on the flat sides of the oval forces the insulation back to its original position. This follows from the fact that a tube of fixed periphery contains maximum volume when it is circular and minimum volume when it is flattened out. The proper action of the oval insulation in accommodating itself to changes in volume is conditional upon the use of a sheath which does not stretch, hence the use of bronze reinforcement. Other reasons for the bronze tapes are given in another section of this paper. The latter also insures that sheath and insulation breathe symmetrically. The reinforced sheath is designed to withstand 500 pounds per square inch internal pressure without rupture.

When 200 pounds per square inch are applied to a lead-sheathed oval cable, there may be as much as 30 or 40 pounds per square inch drop across the sheath during rapid changes in load. With the polyethylene sheath there is a negligible pressure drop, and hence 200 pounds per square inch external pressure will raise the oil pressure within the insulation to approximately 200 pounds per square inch. It should be emphasized that the reinforced polyethylene sheath is subjected at all times to a balanced pressure, that is, if the external pressure rises and falls, the internal oil pressure will rise or fall by an equal amount simultaneously. It will be recognized that if the oil in the insulation is at 200 pounds per square inch, any traces of gas film that might conceivably be present in the cable as manufactured will go into solution within a matter of minutes.

When the cable with polyethylene sheath cools, the external pressure will be communicated without appreciable drop and without time lag to the conductor. But upon sudden loading of the cable there may be local increases of pressure in the vicinity of the conductor. It is here that the oval form is again beneficial in that serious pressure differentials cannot be built up. In solid cable of circular cross-section, pressures at the conductor of 125 pounds per square inch have been observed when maximum load has been thrown on a cold cable[5] and indeed it is possible to burst the paper tapes at the conductor in this manner. Although solid type oil-paper insulation is thought to expand as a whole up to some limiting temperature, for example, about 60 degrees centigrade, due to the elastic properties of the paper and the sealing effect of the viscous oil, nevertheless an irreversible change may take place if the cable is heated to 70 degrees centigrade or higher, as is shown by increase in ionization factor. This is due to the oil at the center flowing outward through the interlayer spaces. Before such flow can take place, in a cable of circular cross-section, very considerable pressures may be built up at the center of the cable.

Now consider a cable of oval cross-section. When the oil at the center expands, the paper tapes distend along the minor axis with no appreciable increase in pressure. It is for this reason that an oval cable behaves reversibly on the load cycle at temperatures at least 10 degrees centigrade higher than a round cable.[6] Callender's Cable and Construction Company manufactured and installed 66-kv solid cable of oval form prior to 1936. The only reason that such cable did not gain general currency was that oil-filled cable was coming into general use at this voltage. At lower voltages sector-type cable is usual and this, of course, is essentially oval in form; in fact, the markedly superior load cycle stability of the oval form probably accounts for the dielectric strength of sector type cables being equal to that of cables with round conductors despite the sharp radius of the sector conductor shoulders.

Operation without Pressure

Should the external pressure be lost, the compression cable may be safely operated without pressure for periods up

Figure 3. Voltage versus time-to-breakdown for solid cable with and without pressure

Figure 4. Effect of load cycling on ionization of 132-kv compression cable

to 48 hours. This valuable characteristic arises from the fact that the sheath and insulation have been compacted, and as a result the pressure effect persists even when pressure has been removed, curve *C*, Figure 2. Apart from this consideration, the normal life of the cable, operated as a solid cable without pressure, is over 1,000 hours, curve *A*, Figure 3.

An unexpected feature of the polyethylene-sheathed compression cable, described in another section of this paper, adds greatly to the safety of 48-hour operation without pressure. This is the complete mechanical reversibility of the polyethylene sheath cable construction. Even with no external pressure, the cable will return of its own accord to its normal ovality under no-load conditions from the more nearly circular shape it assumes under full load. Hence even without pressure, little or no ionization develops for considerable periods of time.

Working Stress

The early compression cables were designed with a limit of 210 volts per mil maximum stress. As cable materials and construction improved, this value was raised. The 260-kv Arnhem experimental cable operated at 425 volts per mil for 250-load cycles to 68 degrees centigrade satisfactorily. In 1939, in London, compression cable manufacturers agreed on a maximum stress of 300 volts per mil, and several installations in 1940 and following employed a value of 260 volts per mil. More recently the economics of the self-contained compression cable have forced British manufacturers to adopt a working stress of 375 volts per mil at the conductor surface for voltages of 132 kv and above. These values compare favorably with the maximum permissible value of 245 volts per mil at the conductor for oil-filled cable in this country.

Comparison with the Oil-Filled Cable

As T. R. Scott[7] has shown, after Hochstadter had spent many years in perfecting a simpler and more economic system than the Pirelli oil-filled cable, it became obvious upon close analysis that both the compression and Pirelli systems employ the same elements, namely, a compressed gas cushion in reservoir or pipe, a flexible membrane in reservoir bellows or sheath, and oil flow in and out of the insulation longitudinally or radially. In the compression cable the sheath itself is a distributed membrane with an almost imperceptible "stroke." The cable is its own reservoir, and due to its oval form is automatically self-compensating. Although the same elements were employed, simplicity and freedom from a multiplicity of accessories had been achieved in the new system.

Review

Arising from the fact that extra-high voltage underground cables are frequently tied to overhead lines and must be capable of withstanding severe transients, and arising from the present economic pressure to reduce underground costs, a successful extra high-voltage cable system must meet five main requirements. These are

1. A high factor of safety against breakdown.
2. High factor of safety must be permanent throughout operating life.
3. Low installed cost.
4. Relative absence of maintenance costs.
5. The cable must be easy to install, requiring a minimum of trained supervisory personnel.

It is believed that the polyethylene-sheathed compression cable fully meets all five requirements. The factor of safety against breakdown is exceptionally high. The sheath, applied at the factory immediately the cable is taken from the impregnating tanks, makes the cable a factory-sealed unit throughout shipment, installation and operating life, hence the high initial factor of safety is maintained permanently. The installed cost is a minimum owing to efficient use of cable materials, absence of sheath stripping operations, absence of complicated accessories, absence of need for coating the inside wall of the pipe, since with a sheathed cable the pipe is merely a duct; and owing to the need for only one treating and filling operation of the entire line instead of many. Maintenance should be negligible. Manufacturing operations are confined exclusively to the factory, so that a minimum of critical operations remains to be done in the field.

The redesigned and simplified compression cable, as constructed for the 138-kv New York–Long Island installation, appears to have met the needs of the industry for a system economical both in initial cost and maintenance.

Characteristics and Development of the New York–Long Island Poleythylene Sheathed Compression Cable*

Purpose of the Tests

The realization that the lead sheath of a compression cable might be replaced by one of polyethylene, grew out of the discovery that polyethylene, supported under pressure so as to prevent swelling, could be maintained indefinitely in oil at much higher temperatures than had hitherto been considered safe.

This led to the manufacture and testing of a series of polyethylene sheathed cables, to ascertain the characteristics required for a successful design.

The support adopted was a pair of suitably cushioned bronze tapes over the sheath.

The following summarized tests are a selection from the large number made on compression cable both before and after the manufacture of the New York–Long Island tie line was started. The earlier tests were primarily to guide design; the later ones, to check operating characteristics. They are, however, not presented in order of date.

Cable Design

The New York–Long Island cable design is shown in cross-section in Figure 5. Its special features are the oval-shaped 350,000 circular-mil conductor, the 63-mil extruded polyethylene sheath, supported by bronze tapes, and the three *D*-shaped skid wires applied with a lay of 12 inches. The insulation thickness, 560 mils, is the same as that used for oil-filled

* W. A. DelMar and E. J. Merrell.

Figure 5. Cross-section of cable

Figure 6 (left). Change of ovality ratio with internal pressure

Figure 7. Voltage stress as a function of time

cables of the same voltage. It will be noted that the ovality ratio, that is, the ratio of the minor to the major axis, over the bronze tapes, is 0.85 and that is the value aimed at in extrusion. In the actual cables, however, the ovality ratio at room temperature and without external pressure becomes about 0.90 due to the elasticity of the sheath, a characteristic of considerable value in the event of loss of pressure.

The New York–Long Island line consists of three such cables installed in a steel tubing (5.5 inches inside diameter, 6.0 inches outside diameter) filled with oil at 200 pounds per square inch.

Manufacture

The manufacture of compression cable follows, in general, the usual procedures for solid-type paper insulated cables up to the point of application of the sheath.

The oval-shaped conductor is formed by roller dies in much the same way as sector conductors.

Upon removal of the cable from the impregnating tank it is taken immediately to the polyethylene extrusion machine which is equipped with dies especially designed for application of large diameter sheaths. The cable is under strict temperature control from behind the extrusion machine until it reaches the take-up reel, this being of the utmost importance to obtain uniform sheath thickness and freedom from strains.

The polyethylene and bronze tapes were applied in the next operation and the skid wires in a final one, bringing the cable to the shipping reels.

Tests were made on each length, without pressure, as follows:

129,000 volts for 15 minutes
Ionization at 20 to 100 volts per mil

Tests on lengths of 35 feet under shield were made with 200 pounds per square inch oil pressure for power factor versus temperature up to 80 degrees centigrade and the same lengths used for breakdown voltage in accordance with Association of Edison Illuminating Companies' (AEIC) procedure.

This last test was made as follows:

6 hours at 190 kv
3 hours at 224 kv
3, 6, or 12 hours at 275 kv

No failures occurred. One test included a splice. No higher voltage was attempted due to limitations of the terminals.

Carrying Capacity

The conductor size of the New York–Long Island line was selected to carry a load of 100,000 kva at 138 kv and 70 per cent loss factor* with a conductor temperature of 70 degrees centigrade and ambient temperature of 18 degrees centigrade. The thermal resistances and resistivities used were as follows:

Item	Thermal Ohms Per Foot	Thermal Resistivity in Degrees Centigrade Centimeter Units
Conductor to sheath	2.96	550
Sheath and protection	0.17	320
Oil	0.46	110
Pipe covering	0.52	215
Earth	4.97	90 (net)
Total	9.08	

Ignoring dielectric loss, the calculations gave a temperature drop from conductor to pipe, of 21.5 degrees centigrade with 400 amperes load. Laboratory tests with the same current and without voltage gave a temperature drop of 21 degrees centigrade, thus affording a partial check of the calculations. It is to be hoped that the operating companies will obtain more data on this characteristic, with special reference to the earth factor.

* Ratio of mean-square current during 24 hours to mean-square current during hour of maximum load.

Check of Adequacy of the Ovality

The ovality of the New York–Long Island cable was designed to be such that expansion of the insulation would never bring the cable to a circular cross-section with any overload likely to occur. Tests were made on cables of ovality ratios 0.90 to 0.92. Tests were made in two ways; first by creating pressure by heating and second, by applying oil pressure mechanically from an outside accumulator.

For the first test a cable of ovality ratio 0.90 inch was formed into a closed loop and placed in an oven, without external pressure, at 75 degrees centigrade and left overnight. It was then allowed to cool to room temperature. The following measurements show the change of ovality ratio.

Temperature Centigrade	Ovality Ratio Minimum/Maximum Diameter
20	0.90
75	0.93
25	0.88

For the second test, a closed loop of cable was again used but, this time, in combination with a Greer accumulator and pressure gauge. The accumulator was connected by a pipe to the conductor, and oil pressure applied in cycles of increasing magnitude, but reducing to atmospheric pressure between steps.

It will be seen from Figure 6 that the ovality ratio rose from 0.92 to a maximum of 0.97 and that an ovality ratio of less than 0.96 is reached with the highest pressure shown in Figure 9.

When the pressure was dropped to atmospheric after each application of pressure, the ovality ratio returned to its original value of 0.92.

Effect of Polyethylene on Cable Oil

Polyethylene was dissolved in cable oil at a high temperature, in various proportions, and subjected both to oxidation and electronic bombardment. Neither rate of oxidation, or deterioration under bombardment was affected by the presence of the polyethylene.

Resistance of Sheath to Oil

The cable design for the New York–Long Island line is based on a conductor temperature of 70 degrees centigrade, which was estimated to give a sheath temperature of about 53 degrees centigrade at normal load. In order to take care of overloads and give a suitable factor of safety, tests on polyethylene in oil were made at 70 degrees centigrade.

Two kinds of tests were made, one on strips of the sheath material, the other on sheathed cable.

The former tests were made on strips of polyethylene 80 mils thick by 1/4 inch wide and 2 inches long. They were immersed in open test tubes of oil and maintained at 70 degrees centigrade for one year. Measurements of thickness were made after 1, 26, 51 and 365 days. It was found that the samples immersed in oils of viscosity index 80 and higher stabilized within a month at approximately 1 per cent increase in thickness. There was no shrinkage in any direction. Oils of low viscosity index, caused a much greater swelling, 6 per cent in the case of an oil which had a viscosity index of about zero.

An oil viscosity index 80 and viscosity 33 centistokes at 210 degrees Fahrenheit was chosen for the cable insulation and one of the same viscosity index, but having a viscosity of 10.3 centistokes at 210 degrees Fahrenheit for the pipe filling.

The tests on cable sheath were made on cable of the following construction:

1. Conductor.....600,000 circular mils.
2. Paper insulation...435 mils.
3. Perforated copper shielding tape.....3 mils with intercalated paper.
4. Polyethylene sheath.....80 mils.
5. Two bronze tapes, staggered.....each 5 mils.

The ends were sealed and the cable laid in a trough of oil which was maintained at 70 degrees centigrade except for occasional reductions to room temperature.

After nine months, the cable was removed and cut open. The polyethylene was in perfect condition and had increased slightly in tensile strength.

Dielectric Strength of Cable

Due to the difficulties inherent in breakdown tests of 138-kv cables, especially where terminals must be constructed to withstand very high voltages for considerable intervals of time, tests were made on 4/0 American wire gauge cable with 220 mils of insulation, which has an oil-filled cable rating of 44 kv. This cable had a copper shielding tape and a 63-mil polyethylene sheath. The tests were made by applying a series of selected voltages as rapidly as possible and noting the times to failure. The results are shown by the solid curve of Figure 7.

Taking into account the fact that the final points on Figure 7 are "withstand" points, it appears that the cable should withstand a maximum stresss of about 1,000 volts per mil continuously at 200 pounds per square inch. The operating maximum stress of the tie line cable is 280 volts per mil calculated on the basis of the smaller diameter, so that the thickness of insulation is not determined by 60 cycle dielectric strength.

Some of the lengths of cable tested included the regular joints but no joint failure occurred.

The minimum impulse withstand voltage recommended for 138-kv cable by Halperin and Shanklin is 672-kv and that recommended by a joint AIEE–EEI* Committee, 650 kv. Tests made at Detroit by courtesy of L. I. Komives of Detroit Edison Company on samples of the New York–Long Island cable, gave an average of 765 kv. One sample included a joint but failure occurred in the cable.

The cable was made with Titebilt construction with the denser, more elastic paper outside. This was adopted here because extremely high-impulse strength was not required and load-cycle tests have demonstrated that the Titebilt construction would have more stable characteristics if required to operate under emergency conditions without pressure.

Cable of identical construction and dimensions, except that it had several layers of high specific gravity paper adjacent to the conductor, was tested at Detroit and broke down at 910 kv. Higher values are attainable with further modification of the taping and such constructions may be used where local conditions prescribe an unusually high impulse strength.

It thus appears that oil-filled cable insulation thicknesses assure a wide margin of safety for impulse strength.

Effect of Strand Shielding

A cable without strand shielding was tested and the results shown by the lower broken curve of Figure 7. The ratio of the breakdown stresses with and without conductor shielding will be found to approximate very closely to Levi-Civita's theoretical stress factor, indicating that at 200 pounds per square inch the effect of strand shielding is solely to smooth out the conductor surface, as would be expected in an ionization free cable.

Effect of Pressure on Dielectric Strength

The cable described previously with strand shielding, was tested for dielectric strength at various applied oil pressures with the following results:

Gauge Pressure Lb Per Sq In.	Maximum Stress (25 Degrees Centigrade) Volts Per Mil at Breakdown
15	750
50	1,060
100	1,270
150	1,420
200	1,510

The AEIC step procedure was followed, the final step only being considered, without reference to its duration. The maximum stress was calculated by the usual formula.

Power Factors

The following power factors are typical of those obtained on routine tests. They are approximately half the guaranteed values, which were the same as those specified by AEIC for oil-filled cable.

Temperature, Centigrade	Power Factor Per Cent
30	0.36
40	0.34
50	0.33
60	0.34
70	0.37
80	0.45

Measurements were made at 80 kv (phase voltage) and 200 pounds per square

* Edison Electric Institute.

inch, the entire cable being at the temperature stated.

Zero Sequence Impedance

Zero-sequence impedance tests were attempted on laboratory lengths, using the set-up shown in Figure 8. About all that could be learned from them was that the magnetic effect of the steel pipe was not an important factor. Laboratory tests do not check with field tests because, although the pipe is insulated along its length, it is grounded at the ends and the earth constitutes a significant part of the circuit. Zero-sequence impedance can be measured only on the line itself and it is hoped that the discussion will bring out data so obtained.

Shunt Capacitance

The measured shunt capacitance is 0.074 microfarad per 1,000 feet.

Pressure Differential

When pressure is applied to the oil in the pipe, substantially the same pressure appears almost immediately at the conductor. In other words, there is no measurable pressure differential due to the stiffness of the sheath, as occurs in the European lead-sheathed compression cables, so that low-pressure spots cannot occur when load falls off.

With rising load, however, a very considerable pressure is required to bring the ovality principle into play.

When current increases in the cable, the pressure rises until it is sufficient to alter the ovality to that corresponding to the increased loading.

The magnitude of this pressure depends on the current, its rate of rise, the thermal capacity of the cable system and the radius, within the cable, at which the pressure is measured.

The pressure is a maximum under the following conditions.

1. Full load current applied suddenly and maintained constant.
2. Thermal capacity at minimum, with pipe in air.
3. Pressure measured at conductor.

Under these conditions, the pressure rose in seven hours to a maximum of 107 pounds per square inch over the pipe oil pressure and then, the current remaining constant, fell off to 27 pounds per square inch over the pipe oil pressure in 24 hours.

This pressure is much lower than those experienced with the European compression cables having lead sheaths.

Figure 8. Zero-sequence impedance

The rise and fall of pressure are shown in Figure 9.

Due to the fluctuating character of the load expected on this line, with its predicted 70 per cent loss factor, and the greater thermal capacity of a buried pipe system, it is expected that the pressure differential will seldom reach the maximum attained in this test.

When a cable is heated under 200 pounds per square inch pressure by current, to 70 degrees centigrade conductor temperature, and the external pressure released to atmospheric, at the rate of five minutes for each 25-pound change, the pressure at the conductor falls as follows in relation to the external pressure.

External, Lb Per Sq In.	Internal, Lb Per Sq In.	Difference, Lb Per Sq In.
200	208	8
175	187	12
150	165	15
100	123	23
50	78	28
0	55	55

The final internal pressure of 35 pounds per square inch dropped to 25 pounds per square inch in three hours and remained at this value for at least two more hours.

Amount of Pipe Oil Expansion Under Load

An experimental length 40 foot long, of pipe and cable similar to that used on the New York–Long Island line was installed in the laboratory. The conductors were Y-connected for current loading and the pipe sealed except for means to move oil in and out, at the ends.

Figure 9. Pressure differential between cable and pipe oil with constant load

The pipe was covered with air-cell insulation to give a total thermal resistance equal to that calculated for a buried pipe.

Constant pressure of 200 pounds per square inch was maintained during load period and the expansion determined by letting out the expanding oil. Conductor temperature was measured by copper resistance; pipe temperature and ambient, by thermocouple.

The total oil expansion for a normally loaded cable from no load to full load (47 degrees centigrade rise) was 3.22 cubic feet per 1,000 feet of pipe over a 20 hour period.

Tests were also made with conductor temperature raised to 93 degrees centigrade, in which case the total oil expansion in 20 hours was 4.54 cubic feet per 1,000 feet.

These tests determined the necessary oil reservoir and pumping capacities for normal and overload operation.

Rate of Oil Expansion in Pipe

In the course of the tests described before, the maximum rate of flow of oil was determined.

It was found to be 10 cubic centimeters per foot per hour or 0.000168 cubic inch per foot per second during the first three hours with normal loading and 13.3 cubic centimeters per foot per hour or 0.000224 cubic inch per foot per second with loading to a conductor temperature of 93 degrees centigrade.

Assuming 10 cubic centimeters per hour per foot of pipe, a rate of 3750 cubic centimeters per minute is obtained as the average rate of flow for 45,000 feet.

Pressure Drop in Pipe

The pressure drop at these rates of flow was determined with oils of various vis-

Figure 10. Details of one conductor of the joint

cosities. The drops were found to agree very well with Poiseuille's formula for viscous flow in pipes provided that, for oils of suitable viscosity, the effective diameter of pipe is taken as about 70 per cent of the equivalent diameter of the cross-section of oil, that is pipe minus cables. Using Poiseuille's formula with this correction and assuming a pressure rise of 100 pounds per square inch at the minimum expected operating temperature of the cable, 40 degrees Fahrenheit (4.5 degrees centigrade), and assuming feed from one end of the line, it was found that the oil should have a viscosity of not over 1,000 centistokes at 40 degrees Fahrenheit. This order of viscosity was obtained by mixing the cable oil with an oil of the same electrical quality but of lower viscosity, the mixture having the same viscosity index as the cable oil. A low viscosity is desirable from the standpoint of avoiding excessive pressure drop in the pipe during conditions of maximum flow However, if for any reason the pipe oil should mix with the cable oil it is advantageous to have the viscosity high and to have the oil compatible electrically with the cable impregnant. The pipe oil viscosity was selected as a compromise between these conflicting requirements.

Splices

A series of tests bearing on development and operation of splices, including impulse tests were also made, but cover too many details to be included in this summary. The impulse strength was higher than that of the cable.

Among the tests were those to determine the effect of humidity on the paper tape power factor during splicing. It was found that exposure of the bared insulation, in situ, to air of relative humidity 50 per cent, at 30 degrees centigrade caused a rise of tape power factor, from 1.3 to 2.2 per cent (100 degrees centigrade) in 25 minutes, but that this could be prevented by keeping the insulation protected with plain polyethylene tape, and not basting.

Basting with fresh oil at 120 degrees centigrade had the same initial effect, but the polyethylene tape protection was preferred because of danger of the basting oil becoming oxidized from continuous overheating and handling. Tests showed that continued basting with the same oil resulted in a rise of tape power factor. Basting was rejected also because the hot oil removed cool surface oil and replaced it with hot oil which would contract into the paper upon cooling.

Load Cycle Tests

Preliminary load cycle tests were made on single cables in brass pipes in order to obtain data for designs and then to check designs.

Some of these tests were made with voltage and current and others with current only. In some cases joints were included in the tests.

Tests on a 90 foot replica of the tie line, that is, with three cables in a steel pipe, were started at 25 per cent over rated voltage with current to bring the copper to 70 degrees centigrade. Due to electrical failure of a transformer, it was necessary to reduce the voltage to three-quarters the rated value and continue the test on this basis through 49 load cycles of 48 hours each, with current on for half this period. The power factor at 70 degrees centigrade and rated voltage remained unchanged at 0.31 per cent and the final ionization factor (11 kv to 100 kv) was 0.04 per cent at 28 degrees centigrade.

Upon restoration of the original transformer, the test was resumed at the original voltage (100 kv conductor to ground), but the conductor temperature was raised to 85 degrees centigrade. To date, 21 load cycles under these conditions have been completed and the ionization factor is 0.01 per cent at 28 degrees centigrade. The power factor at 70 degrees centigrade and rated voltage, is 0 34 per cent. It is expected that results of tests over a long period will be available for presentation with the discussion of this paper.

Accessories of 138,000 Volt Compression Pipe Type Cable*

The very simple accessories of the European gas-pressure compression cables are here replaced by the more elaborate pressure control equipment necessitated by the use of oil as the pressure medium. In the design of the accessories, the experience of other pressure systems in this country and abroad was given consideration. Starting with this as a basis, the details of design were developed by Phelps Dodge engineers in collaboration with the company's research laboratory, to fit the requirements of this installation.

The cables, pipes, manholes and installation equipment are covered by other papers of this symposium. This leaves only the cable joints, terminals and pressure regulating equipment to be considered under the heading of accessories.

Cable Joints—Normal and Semistop

Figure 10 shows details of a single conductor of the splice (either normal or semistop).

Compression-type connectors are used, with the indentations rounded out with solder applied with a soldering iron.

The insulation consists of hand-applied pre-impregnated paper tape applied butted. It is of the same grade as the cable insulation.

The polyethylene sheath is carried across the joint by the use of pressure-sensitive polyethylene tape which is applied half-lapped to a minimum thickness of 100 mils, forming a seal from one end of the joint to the other. This also permits grounding of the cable and joint shielding at every splice by zigzagging a thin copper strip through the tape wall and bonding it to the skid wires and armor.

Figure 11 shows the normal joint. The sleeve consisted of eight-inch outside

* J. H. Palmer and W. A. DelMar.

Figure 11. Normal joint

diameter steel pipe and the over-all length was 5 feet 10 inches. The sleeve is in two parts with an annular joint at the center, in order to aid in handling and, at the same time, to allow centering of the splice in the manhole. Welded joints having long heat paths from the weld to the pipe were used for all welds made after the cable was pulled in, to protect the cable from the heat of welding.

Figure 12 shows a semistop joint. The cable splices are the same as for the normal joint, the difference lying in the semistop feature at each end, consisting of glands or stuffing boxes. The packing for these glands is composed of a soft oil-resistant synthetic rubber compound which has been thoroughly tested to prove that it neither affects or is affected by the pipe oil. The varnished cambric build-up under these glands serves a double purpose; permitting a build-up to a close fit without having to make the gland too tight for easy assembly and at the same time distributing the area of transition between a sheath which "breathes" due to thermal expansion and contraction of the cable, and the section of this sheath which is bound down by the gland and not permitted to "breathe."

The sleeve is divided into four parts both because it is necessary for assembly and for ease in handling. The main sleeve is 10-inch outside diameter steel pipe and the over-all length of the joint is slightly over 10 feet.

Safetyheads are used as in other pipe installations. They are set for 500 pounds per square inch and are arranged to relieve either the pressure in the joint, or in either section of pipe connected to the joint, in case of electrical failure. All three safetyheads discharge into an expansion tank which contains a drain valve. If this valve is opened and oil or gas is discharged, a failure of one of the three safety heads is indicated and sectionalizing to isolate the cause may be done by proper manipulation of the valves.

Figure 13 shows a detail of the single conductor cable where it passes through its semistop gland as mentioned before. These semistops follow previous practice, with the exception that the gland makes contact with the oval polyethylene sheath. They are intended for sectional-

Figure 12. Semistop joint

Figure 13. Semistop gland

ization of the line with pressure removed, but tests with the full pressure applied to one side of the stop have shown them to be surprisingly tight either with gas or with oil as respective pressure mediums.

Termination Equipment

Figure 14 shows a schematic diagram of a termination of the system and the relative locations of the various accessories involved.

Except for the base, the terminals are of more or less conventional design and were purchased for this installation from the General Electric Company. They differ from other high-pressure terminals of American design in that the base contains a gland or stuffing box which seals to the cable sheath and coverings, forming a barrier between the pipe and the pressure or stop tube of the terminal This allows the use of cable compound in the terminal stop tube where the compound is in contact with the cable insulation. Pressure is maintained here by connection to the oil in the pipe through two compensators which transmit pressure through oil-resistant rubber bladders, assuring complete separation of the pipe oil from the terminal stop tubes, and substantially equal pressures in the pipe and tubes.

The compensators were manufactured by Greer Hydraulics, Incorporated and were originally built for use with hydraulically-operated devices on airplanes, using oil as the operating medium. They will withstand differential pressures over 2,000 pounds and for service with cable systems should have unlimited life. Our tests show that the oils used do not affect the rubber in the bladders and conversely that the rubber does not affect the oils, even at temperatures much higher than those which will ever be encountered in use. Two compensators are used at each set of three terminals for two reasons:

1. To give a double safety factor against leakage and consequent mixing of the two oils in the system.

2. To allow removal of one compensator at a time for inspection and test without interruption of service.

Figure 15 shows the spreaderhead used to change from a three-conductor system to three single conductor risers. These risers must, of course, be nonmagnetic; thus copper tubes are used.

Note that here again wherever a field braze or weld is required after cable installation a long heat path is provided so that no damage will be done to the polyethylene sheath by the heat. Tests have shown even this to be unnecessary, however, due to the high thermal capacities and conductances involved, and due to the skid wires which space the cable quite effectively from the pipe. The safetyhead is provided to relieve the pressure if oil surges should occur in the pipe. If ruptured, oil would be discharged into the relief tank. This would also serve as a means of locating a cable failure, in the event of failure causing an oil surge. The section in which failure has occurred would be found by opening the drain valves on the relief tanks both at the spreaderheads and at the semistop joints to see if the safetyheads have ruptured.

Pressure Control Station

Figure 16 shows the equipment in the pressure control station. This is quite similar to that used for other oil-pressure cable systems in this country. On this system, one such station is located at each end of the line. The line will operate from the controls at either end, one being used as a standby for the other.

The purpose of this equipment is, of course, to maintain the pipe oil pressure between allowable limits (200 pounds per square inch ± 20 pounds per square inch) during thermal expansion or contraction of the system due to load and ambient temperature changes. This is accomplished as follows:

1. If the pipe pressure falls to 180 pounds per square inch, due to thermal contraction, one of the pressure control switches will close, starting the oil pump. When the pump brings the pressure to 200 pounds per square inch, the same switch will open, stopping the pump. If the pressure increases to 220 pounds per square inch, due to thermal expansion, one relief valve will start passing oil back to the reservoirs, thus dropping the pressure. If this valve for any reason fails to relieve the pressure rise, a second one in parallel with it will operate. The tanks provide reservoirs for this necessary surplus oil. The oil is stored in these tanks under an atmosphere of dry nitrogen to prevent oxidation. Nitrogen pressure is maintained between 4 and 15 pounds per square inch by conventional gas pressure regulators and a 220 cubic foot gas tank.

Figure 14. Schematic diagram of termination

Figure 15. Spreader head

Figure 17. Instrument panel in control station

Alarm contacts are provided to give alarms for the following:

1. High or low oil level in the tanks.
2. High or low gas pressure over the oil.
3. Too long time of operation of the oil pump, indicating a leak.
4. Too high or low pressure in the pipe line.
5. Low oil pressure in the terminal oil lines.

Figure 17 shows the instrument panel included in the control station.

Instruments are provided for the following:

1. Indication and recording of pipe pressures.
2. Oil level in tanks.
3. Nitrogen gas pressure over the oil in the tanks.
4. Indication of time of oil pump motor operation with alarm contacts for excessive time.

All of the foregoing equipment shown in Figures 16 and 17, including the oil tanks, is enclosed in a house in which the temperature is maintained at 65 degrees Fahrenheit or higher by an electric space heater.

This assures fast and accurate operation of the controlling and indicating instruments which might be slowed down or even put out of operation if the oil in these small lines were left at ambient temperature in the winter.

Figure 16. Equipment in pressure control station

Installation of the 138,000-Volt Polyethylene Compression Pipe-Type Cable*

Location and Description of Route

The first 138,000-volt compression pipe-type cable with an extruded polyethylene sheath is installed in a line between the Jamaica substation of the Consolidated Edison Company of New York, Inc. and the Valley Stream substation of the Long Island Lighting Company, a total distance of approximately 8.2 miles of which 5.7 miles is in the Con-

* C. T. Hatcher and E. F. DeTurk.

Figure 18. Tie feeder connections in New York metropolitan area

Figure 20. Elevation of normal joint manhole

solidated Edison territory and 2.5 miles in Long Island territory. The line will be used for interchange of power between the two systems depending upon the requirements in each system from time to time.

The route of the line lies wholly within city areas and traverses heavy traffic areas through paved streets. This tie line in relation to other tie lines in the New York metropolitan area is shown in Figure 18.

Figure 19 shows diagramatically the connections at the Jamaica substation of the Consolidated Edison Company and the Valley Stream substation of the Long Island Lighting Company. At the Long Island terminal, connection is made to a double 66,000-volt bus through 2—30,000/50,000 kva 3-phase 138/66-kv transformers in parallel. Each of the two transformers is connected to a 66-kv bus section and these two bus sections are normally connected through a tie circuit breaker.

From this bus, power flows into or out of the Long Island system through numerous 66-kv feeders. The Consolidated Edison terminal connection is made to either the east or west bus sections of a double 138,000-volt bus with an oil circuit breaker between the cable and each section of bus. The buses are tied together through a tie oil circuit breaker. Power flows into or out of the Consolidated Edison system from these buses through 2—138,000-volt feeders connecting to the Consolidated Edison Hudson Avenue Station.

Figure 19. Consolidated Edison System—Long Island Lighting Company interconnection

Pipe and Manhole Construction

Prior to installation of the pipe a complete survey of the proposed route was made. After selection of the tentative route all known sub-surface structures such as water and gas mains, sewers, communication structures and company-owned structures were plotted to scale on drawings. Superimposed on these drawings were all projects contemplated for future construction, data for which were obtained from utility, city and state officials. On these composite drawings the lane required for the line was laid out so as to avoid existing and future sub-surface structures.

The pipe used was six-inch outside diameter seamless steel tubing having a 1/4 inch wall thickness. The pipe was cleaned externally and internally at a central cleaning and coating plant. After cleaning, the inside of the pipe was coated

Figure 21. Elevation of semistop joint manhole

Figure 22. Installation of precast manhole

Figure 24. "A" frames mounted on wheels facilitate placing pipes in trench

with a lacquer made by the Dearborn Chemical Company. The outside of the pipe was coated with 1/2 inch of Somastic—a mixture of asphalt, limestone, sand, and asbestos fibre.

In order to provide for future increase in tie capacity two 6-inch pipes were installed. The two pipes were installed in a common trench on 18-inch centers and to a nominal depth of 4.5 feet. This spacing was selected after calculations had been made of the heat dissipation when both lines were fully loaded.

A study of allowable pulling stresses in the cable indicated that straight sections should be held to approximately 2,000 feet. In those sections where it was necessary to include offsets or bends, either horizontal or vertical, pulling tensions were calculated and the section length was chosen so as not to exceed a tension of 8,500 pounds per square inch (approximately 7,000 pounds total pull) in the copper or a maximum length of 2,000 ft., whichever proved to be limiting. Manholes were used for splicing the cables. Consideration was given in the Long Island section to burying the splices to eliminate the cost of permanent manholes. Temporary collapsible manholes would have been used during splicing and removed after completion of the cable joints and the entire opening filled in and paved over as for the remainder of the cable trench. Permanent manholes were finally decided upon because the route lay along the middle of a heavily traveled street

Figure 23 (below left). "Pig" used in making internal pressure test of pipe welds at 500 pounds per square inch

Figure 25 (right). Representative section lengths and measured pulling tensions

Figure 26. Arrangement of equipment for blowing pull wire into pipe

Figure 28. Internal arrangement of normal joint

with concrete paving. A second manhole excavation would otherwise have been required if a second cable were installed, and this would be expensive and objectionable to the civic authorities.

The manholes were of precast concrete construction that is, they were poured at a central plant and transported to the field for installation. In the New York section of the line semistop and normal joint manholes were used and in the Long Island section only normal joint manholes were used. Figures 20 and 21 show the normal and semistop joint manholes. Two roof openings were used to facilitate installation of the cable. Oversized pipe sleeves were cast into the end walls so as to provide flexibility for installing the pipes in the manholes. Figure 22 shows a precast manhole wall section being lowered into the street opening.

The pipe was delivered in approximately 40-feet double random lengths. Upon delivery of the pipe to the street location the random lengths were arc welded together above the trench wherever possible. The pipe ends were flared for use with chill rings. Welds were made in three passes and each welder was required to make qualifying welds. Upon completion of a weld it was tested internally with 500 pounds dry nitrogen gas and with the outside of the weld surrounded by a trough of water so that leaks could be detected. The gas pressure testing was greatly expedited and the amount of gas kept to a minimum by the use of a test "pig." This device is about 30 inches long and consists of two steel reinforced rubber "tires" connected together by a steel linkage in the center. This "pig" was inserted in the ends of the pipes to be welded together, so that the weld was over its center. After the weld was made the "tires" were inflated with 600 pounds nitrogen pressure, and the pipe section between the two "tires" and including the weld was then tested at 500 pounds pressure as described before. Gas was supplied through two hoses leading out the open end of the pipe line. When the test was completed, the gas pressure was released and the "pig" pulled out the open end of the pipe by means of a pulling line. This test pig is not new for this work and is believed to have first been used in this country on the recent New Orleans pipe cable installation. Figure 23 shows the "test pig."

After several lengths of pipe were welded and tested they were suspended over the trench from chain hoists attached to "A" frames and were then lowered into the trench or pulled into the trench under structures. Figure 24 shows the A frame method of lowering the pipe. The welded sections of pipe after being placed in the trench were welded together in place until a section between manholes had been completed.

The route of the cable crosses several

Figure 27. Cables are fed into feeding tube over large diameter sheave

Figure 30 (left). Typical section of controlled humidity chart

Figure 31. Sectional view of 161-kv terminal for compression cable

brooks, several drainage culverts and a railroad track. At each of those locations, the cable pipe was laid inside of a ten-inch cast-iron pipe sleeve. In the case of certain drainage culverts, the pipe was cut directly through the culvert opening in order to avoid the deep pits which would have been necessary to pass beneath the bottoms of the culverts. A large part of the route in the Long Island section is below the normal water table and considerable pumping and stream by-passing was necessary to allow satisfactory pipe installation. Upon completion of a section between manholes and after some back-filling had been completed the pipe was subjected to an internal air pressure of 500 pounds and a pressure drop test was made. The air pressure was provided by a special compressor capable of supplying 500 pounds pressure and equipped to remove moisture from the air. Prior to raising the pressure to 500 pounds the pipe was flushed with dry air from the compressor until a maximum dew point of −30 degrees centigrade was reached at both ends of the pipe.

In order to prevent damage to the pipe coating a bedding of clean sand free from stones or similar objects was placed in the bottom of the trench. A cushion of clean sand was also placed around and over the pipes before the remaining fill was bulldozed into the trench.

The Somastic coating was tested electrically upon receipt at the central receiving yards and again before the trench was back-filled, so as to determine if the coating was free of voids or other damage which might cause future corrosion troubles. The welds were also coated with Somastic by means of a mold and were tested electrically to determine the quality of the coating. Insulation resistance measurements were made on the pipe after back-filling; and, a value above 10,000 ohms per 1,000 foot of pipe had to be obtained before the section was considered satisfactory. Where sections of the coated pipe failed on the resistance test, an interrupted d-c potential was impressed between the pipe and ground and the defect in the coating was located by a survey over the pipe from the street surface. Where breaks in the coating were detected by this method the pipe was exposed and the coating repaired.

Bends were avoided wherever possible, but the route which was followed necessitated both horizontal bends and vertical dips in some sections between manholes. In the majority of cases it was possible to avoid having more than one ninety degree bend in a section; however, in one section this was unavoidable and two ninety degree bends were installed. Examples of typical sections and the actual pulling tensions measured in these sections are shown in Figure 25. Complete records were kept of pulling tensions for all cable sections. The average coefficient of friction for straight sections including minor offsets and vertical dips was found to be 0.242.

Cable Installation

Prior to the installation of the cable it was necessary to install the pipe a small steel line for drawing the cable pulling steel winch line into the pipe. This was accomplished by blowing a "mouse" through the pipe by means of compressed air. The mouse is a disk arrangement to which was connected a 1/4-inch steel line. Figure 26 shows the arrangement of equipment for this operation.

The three single-conductor cables were pulled into the pipe at the same time. Special pulling eyes were installed on each cable at the factory prior to shipment. Due to the use of two manhole entrances it was possible to use a pulling-in tube and a pulling-out tube constructed with rollers for the cable installation. These tubes were coupled onto the pipe during pulling operations.

The 3-cable reels were placed in tandem at one manhole and a special cable pulling winch was used at the other manhole location. The cable was fed directly from the reels over a special sheave and into the pulling-in tube. Approximately five gallons of the cable impregnating oil was fed into the pipe for lubrication during each pull. Figure 27 shows the three cables being pulled into the pipe. After the cables were installed in the pipe, a pipe seal or "night cap" was placed over the cable ends and fastened to the pipe. A positive nitrogen pressure of approximately five pounds was then maintained in the pipe until splicing was begun.

Cable Splices

Both normal and semistop joints were used in the Consolidated Edison section of the line whereas only normal joints were used in the Long Island Lighting section. Where semistop joints were

used, they were installed approximately one mile apart.

Pressed connectors were used to provide mechanical strength in the joint to prevent pulling out of the conductor from the connector during contraction at no-load periods. The joint is paper tape insulated, shielded and has a polyethylene jacket of adhesive polyethylene tapes. Upon completion of the jointing operations the joint casings were placed in position and welded. At semistop joint manholes by-pass piping was installed external to the joint to provide a free passage for the pipe oil around the semistop glands in normal operation. Figures 28 and 29 show the internal arrangement of the normal and semistop joints.

In order to prevent the possibility of moisture being entrapped in the joint installations during construction, humidity control was maintained in the manholes during all splicing operations. The humidity was kept below 55 per cent relative humidity by means of silica gel air conditioners and by bleeding of cool dry air from the spare pipe into the manhole. Two of the manholes in the Long Island section extended about three feet below the water table, and in order to maintain satisfactory humidity conditions it was necessary to line those manholes with a waterproof cellotex lining, with an air space between the lining and the manhole wall. In addition, there was the usual drying and dehumidifying procedure. A typical chart of controlled conditions in a manhole as compared to outside humidity is shown in Figure 30.

Before any joints were constructed in the field, the splicers, foremen and supervising engineers were given careful training in the details of construction and assembly at splicing schools of the operating companies under the supervision of the manufacturer's engineers.

Splicing houses were installed over the manholes to provide protection from the weather, dust and dirt. With this protection it was possible to continue splicing operations continuously after a splice had once been started.

Terminals and Pumping Plant

The line was terminated at each end in three single conductor potheads. A spreader head was welded to the pipe above ground and each of the three cables was installed in a separate copper pipe up to the pothead. The pothead construction is shown in Figure 31.

An oil pumping plant and two 750-gallon tanks are provided at each end of the line. A dual pumping plant at one end of the line or a pumping plant at either end was considered satisfactory and in this installation it was decided to install one at each end. Figure 32 shows the terminal arrangement and pump house at Valley Stream.

Installation of Oil

Upon completion of the joints and the terminals the entire line was evacuated until satisfactory vacuum had been obtained. Oil was transported by tank truck from the manufacturer's plant to Valley Stream where it was pumped into the line. During the filling operation vacuum pumps were operated at the Jamaica end of the line and a check was made of the progress of the oil along the route of the pipe by sampling at semistop joint locations.

Electrolysis Protection

In order to permit checking the quality of the outside pipe coating periodically test stations were provided at each manhole. Test leads were fastened to the pipe outside of the manhole and terminated in a test box in the manhole shown in Figure 33. Insulation resistance can be determined by measuring the resistance of the coating for a known length. Figure 34 shows this connection.

Cathodic protection for the pipe line is provided by connecting the pipe at the Jamaica and Valley Stream terminals to ground through a 2-volt 23-plate grounding battery. With the negative terminal of the battery connected to the pipe, the pipe line is maintained at a negative potential at all points a long the line. Tests made on the grounding battery indicate that in the event of a feeder failure, the battery will carry 15,000 amperes for one second without injury.

Thermal Measurements

In order to check temperature conditions on the line and to obtain data for soil resistivity calculations, the following facilities were provided. At each manhole location in Consolidated Edison territory and at two locations in Long Island territory a thermocouple was attached to each pipe, as shown in Figure 33 and the thermocouple leads were terminated in the manhole. Also at a selected number of locations along the line, thermocouples were installed to measure soil ambient temperature. These thermocouples, placed at the same depth as the pipe, were located at points laterally opposite the pipe thermocouples and at a distance from the pipe sufficient to avoid the effect of

heat dissipated from the pipe. It will therefore be possible to measure the pipe operating temperature under known loading conditions, and from the pipe temperature rise above soil ambient, determine soil resistivity values. In addition to the pipe thermocouple installations, test heater cells have been installed in the vicinity of the soil thermocouples for the purpose of obtaining comparative data on seasonal variation of soil resistivity. It is planned to use such heater cells in the future to explore soil resistivity variation along proposed feeder routes and for other tests in connection with soil resistivity.

Progress of Work

An idea of the time required for the various processes described is given in Figure 35.

Installation of Pipe . . . May 12 to September 5, 1947
Installation of Cable . . . July 30 to September 30, 1947
Installation of Joints . . August 11 to October 10, 1947

Conclusion

From the foregoing it will be seen that new developments are taking place in the field of underground high-voltage power transmission. While all precautions were observed to protect the pipe and cable from contamination by dirt and moisture throughout the installation, the continuous plastic cable sheath provides an additional factor of safety for the cable insulation. The complete integrity of the insulation as produced under controlled factory conditions is maintained from the time the cable leaves the factory until the ends are spliced while the disadvantages of sheath losses and possible sheath ruptures inherent in previous lead-sheathed compression-pipe type systems have been eliminated.

The authors wish to express appreciation for assistance in compiling data for this paper to R. W. Gillette and F. P. West of the Consolidated Edison Company of New York, Incorporated, and to J. L. Davidson of the Long Island Lighting Company and to the electrical engineering and construction staffs of Ebasco Services Incorporated who laid out and supervised construction of the Long Island Lighting Company's section of the line.

Discussion

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): There are a number of points in this paper which warrant careful consideration. It is noted from Figure 6 of the paper that the internal oil pressure rises from zero to 200 pounds per square inch, when the "ovality ratio" (ratio of short diameter to long diameter) changes from its initial value of 92 to 97 per cent. However, calculation indicates that this change in shape can provide for less than 1/4 per cent increase in volume. Even if only 40 per cent of the cable is occupied by oil, this would seem to mean that this change of shape can accommodate only about 8 degrees centigrade change of cable temperature.

These data from Figure 6 should be compared with the data shown in Figure 9 of the paper which, for an unstated ampere load on the cable, show only 107 pounds per square inch increase of pressure and show that this ultimately falls off very greatly.

If the cable of Figure 9 was initially not well saturated or if the system contained, for instance in the pipes or the gauges, air or gas pockets, a condition such as shown in Figure 9 could be expected. That is, the pressure would be much less initially than as found in Figure 6 and would fall off as the gas goes into solution. It will be interesting to have the author's explanation of the seeming discrepancy between the data of Figure 9 and that of Figure 6.

DelMar also cites a test where a closed loop of cable was heated in an oven from 20 to 75 degrees centigrade. The ovality ratio changed only from 0.90 to 0.93. This change of shape corresponds to a volume increase of only about 0.2 per cent. However, it can readily be shown that, in the absence of voids, the volumetric change of the cable structure, largely due to the oil, is around 1.5 per cent for this temperature range. The paper does not make clear how the difference of 1.3 per cent is accommodated.

If we assume for discussion that the cable does not contain within its "seal," this initial "void" of 1.3 per cent of its volume, then this "void" presumably would be produced thereafter by a permanent alteration of the sheath or its reinforcing tapes.

On the assumption that there is an initial void space of 1.3 per cent at room temperature, this space would be increased to about 2 per cent if the cable were cooled to zero centigrade, as a result of the further con-

traction of the saturant. A reduction of ovality ratio to 0.75 would be required to fill this void space. No hydrostatic pressure can be built up within the insulation until it is filled. Hence, unless the insulation can be compressed enough to permit this distortion, is it not likely that the cable will not be a pressure cable at all but will contain ionizable voids at very low pressure, just as does any solid-type cable when operating at low temperature?

Suppose, on the other hand, that the cable Del Mar used in this loop test had been fully saturated at 20 degrees centigrade, then calculation shows that the change in ovality from 0.90 to full circular shape would have accommodated a volumetric change of only 0.4 per cent. The additional 1.1 per cent would have to be accommodated by other means which would seem to require very large hydrostatic pressure, and permanent stretching of the metal tapes and possible extrusion of the polyethylene through the tapes.

The discussion herein of the effect of change of ovality is based upon the assumption of an elliptic cross section of the sheath. It is believed that no important error results from this assumption even when the conductor is much flatter than an ellipse having the same major and minor diameters. Furthermore, a factor has been omitted from this calculation which, if taken into account, would appear to reduce still further the accommodation indicated for change of ovality ratio. This factor is the expansion with temperature of the polyethylene which takes away directly the same amount of possible accommodation for oil expansion.

I would like to have the comments of the authors concerning the possibility that the polyethylene would creep circumferentially around the cable due to the differential mechanical pressures. When the internal temperature is high, the cable is being forced toward a more nearly round cross section by pressure of the sheath on the long axis. The polyethylene adjacent to the long axis is then under large mechanical pressure whereas that on the flat side is under little or no pressure. With the polyethylene at the maximum operating temperature, and thus with minimum resistance to flow, would there not be a circumferential flow, resulting in a thinning of the polyethylene wall at the ends of the oval? The tendency to flow will be in the opposite direction at low temperature, but because of the much greater resistance of the polyethylene to flow at low temperatures, would not the tendency for the polyethylene to flow away from the ends be cumulative?

We do not believe that the foreign operating experience of lead sheathed compression cable is necessarily a valid answer to the foregoing questions or those questions raised by Pettee and others, because the characteristics of polyethylene and lead are inherently different.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Twenty years ago, the AIEE had presented to it a symposium of papers covering the initial commercial installations of oil-filled underground power cable. These installations symbolized cable's coming of age and they were based on developments originated by the Societa Italiana Pirelli. This and the other pipe-type cable paper presented today, together with work done by some other manufacturers on extra high-voltage cable systems in this country, reflect great credit on the American cable manufacturing industry. As in this case, the encouragement of cable users have been of some help in such developments.

For operation at 69 kv, there is a choice of many types of cable systems, including solid-type or oil-filled cable either in ducts or buried, medium-gas-pressure or self-contained high-pressure cable, and an assortment of pipe types. Altogether, there may be 15 types at 69 kv, about 12 types at 138 kv, and an unknown, but smaller number, of types at 230 kv. My point now is that one should not become enamored of any one type, but should approach each situation on a straight engineering basis. As experience develops, however, perhaps a few of the many types will drop out of the picture.

Of course, the simplest installation is of solid-type cable with sealed joints filled with compound and having no oil reservoirs. Such an installation of 69-kv cable was made in ducts in Chicago over five years ago and a similar, but buried, installation is to be made in Winnipeg this year.

Also, a line of low-pressure oil-filled cable should require very little maintenance according to operating experience of recent years. In this connection, there is a psychological problem, since the joints, reservoirs, relays, and so forth in manholes and at terminal structures may be readily inspected and so this is done frequently in some cases; for a pipe-type cable installation, not much can be given periodic inspection and so not much is done. A similar experience occurred when the practice was changed from the use of gasketed covers to welded covers on some liquid-filled reactors and transformers.

In the pipe-type cable installations, there is the possibility of between-phase failures. This means a higher interrupting duty for the existing or required new circuit breakers, or both, than for installations for single-conductor solid-type or oil-filled cable. This higher duty has militated against the use of pipe-type cable in at least one instance.

In some cases, the fact that lead-sheathed cable of any type may be installed in existing or contemplated conduit systems (that may contain other cables) makes the use of pipe-type cable systems economically unattractive.

Extensive field and laboratory tests, running up to 70,000 hours and up to 140 degrees centigrade, on cable samples, supplemented by various test data obtained on paper tapes in oil, have indicated that oil-filled cable may safely operate at higher than the standard values used in this country for oil-filled pipe-type cables. This advantage amounts to about 10 degrees centigrade for normal operation and about 20 degrees centigrade for emergency operation. Perhaps, with more test data and some operating experience, higher operating temperatures than the standard values may also be established for some of the pipe-type cable systems. It would be of interest, for example, to learn what would happen to a 69-kv polyethylene-sheathed compression cable if its conductor were to operate for a week or two up to 115 degrees during an emergency.

Also, it would be helpful to learn the manufacturer's present ideas of the limiting temperature for say, 4,000 hours per year for 40 years, to which polyethylene may be subjected when immersed in oil, as described in the paper. At such temperatures, what is the expected condition of the polyethylene at the end of the assumed 40-year period?

This paper and other information have disclosed some marvelous 60-cycle breakdown test data as obtained in tests taking hours. Such data would indicate that substantial reductions in required insulation thicknesses are in order, especially for some pipe-type installations. However, as has been known for some time, the criterion to use in most cases is the unit impulse strength of the insulation, and this criterion has not disclosed any particular advantage for the pipe-type systems.

Also, Wyatt might expand on his statement about the English adopting a limiting maximum stress of 375 volt per mil for compression cable, because information that has come to my attention up to end of 1947 showed usage up to only 254 volt per mil.

In connection with the description of the taping for the normal joint of the polyethylene-compression cable by Palmer and DelMar, test data showing that the applied polyethylene tape is in effect "a seal" across the joint would have been of interest.

In general, it seems that the pipe-type cable systems will be the most suitable and economical for some conditions for operation at extra high voltages, but the nature and extent of these conditions are still being defined.

M. H. McGrath (General Cable Corporation, New York, N. Y.): The impulse data included in the DelMar section of the paper is interesting in that it emphasizes what would appear to be an inherent limitation of compression cable and one which may often be of importance on circuits connected to overhead lines. The average impulse breakdown strength of the tie line compression cable is given as 765 kv or only 14 per cent above the withstand level considered as standard on the 560 mil wall employed. On the other hand, the impulse strength reported today for the New Orleans cable is about 61 per cent above the standard level. DelMar suggests that this Titebilt construction may have been responsible for the relatively small margin on the tie line cable and cites a test on an experimental modification of Tirebilt on which the margin increased to 35 per cent. However, this is still much less than that obtained on the New Orleans cable. We can readily agree with DelMar's inference that adoption of the conventional taping practice will yield an improvement over Titebilt, but question whether this is the complete answer. An important factor in the problem appears to be the oval-shaped conductor which must be employed in the compression cable to obtain proper diaphragm action. By way of example, if one accepts the maximum stress obtained by DelMar on the tie line cable as the governing factor on impulse, we find that a round conductor with approximately the same perimeter as the oval conductor used would give the same impulse breakdown strength with a 460 mil wall as was obtained on the tie line cable with 560 mils. In other words, for the same surge strength a round conductor would have required 18

per cent less insulation thickness than was actually used. On normal frequency the maximum stress at rated voltage on the previously mentioned round conductor with 460 mils would be no greater than that accepted for the oval-shaped conductor with 560 mils. While it is true that the average stress on the round-conductor construction would be higher than on the tie-line cable, it would appear from the emphasis placed by DelMar throughout the paper on maximum stress that he considers the latter to be proper criterion at normal frequency.

A statement appears in the paper to the effect that the long lay skid wires reduced the coefficient of friction from 0.39 to 0.23. Presumably the 0.39 figure is intended to be representative for the usual skid wire construction in which the spacing between turns is about 1.5 inches. This value is materially higher than the 0.30 figure found in Table I of another paper[1] for straight pulls on the New Orleans installation where a short lay skid wire was used.

It seems possible that other factors may favor the use of long lay wires on compression cable. For example, might not a short lay wire tend to restrict the diaphragm action so essential to the satisfactory operation of compression cable? It would be interesting to know whether the tests reported on pressure differential and other characteristics of the diaphragm were made with the skid wires taut. Such a condition might occur in installation or service and interfere materially with the symmetry of the "breathing" action of the diaphragm.

It is also pointed out in the paper that one of the disadvantages of the lead covered compression cable design is the energy loss in the sheath. It might be mentioned that in the American design of unarmored lead covered compression cable, operation with open-circuited sheaths was contemplated because the heavy saturated webbing tapes used over the diaphragm reinforcement were designed to serve both as mechanical protection during installation and as low voltage insulation between sheaths and between sheath and pipe. It is easy to overlook the fact that energy losses comparable in magnitude to those with short-circuited lead sheaths can be introduced with skid wires, particularly if such wires are of high conductivity material and are applied with a long lay. For example, on the New York-Long Island compression cable, the energy loss in the skid wires, which we assume are copper, is estimated at from 50 to 75 per cent of the energy loss in a lead-covered compression cable operating with short-circuited sheaths. On the other hand, if a short lay construction had been employed, it is estimated that about two-thirds of energy losses in the skid wires of the tie-line cable could have been eliminated. The importance of this matter on the larger sizes of pipe type cable now being used in this country is obvious.

REFERENCE

1. 115-KV HIGH-PRESSURE OIL-FILLED PIPE CABLE INSTALLATION AT NEW ORLEANS, LOUISIANA, W. R. Bullard, A. D. Pettee, G. L. Rhodes. AIEE TRANSACTIONS, volume 67, 1948, pages 475–86.

A. D. Pettee (General Cable Corporation, New York, N. Y.): Throughout the first section of the paper one gains the impression that if a permanent polyethylene sheath is used on high-pressure pipe cable, fewer precautions are needed to avoid the harmful effects of moisture, and of contaminants which might be found in the pipe; also that less precautions need to be taken in installing the cable in rainy weather; further, that the sheath makes unnecessary a coating on the inside of the pipe.

The last section of the paper, however, indicates that exactly the same precautions were taken with this cable as have been taken with other pipe cables, which have not thus included in their construction a permanent sheath. The pipe in this case was carefully cleaned and coated internally, it was flushed with dried air to a minimum dew point, a plunger was blown through the pipe, the entire line was evacuated prior to filling, and provision was made for a tarpaulin cover to protect the cable if installed in wet weather.

In other words, none of the usual precautions for such installations were dispensed with, in spite of the existence of the permanent sheath. It is difficult to see the value of the extra factor of safety which is mentioned, since entirely adequate protection can be and has been provided in a less complicated manner, for example as is described in the paper discussing the New Orleans pipe-cable installation.

Secondly, in the first section of the paper, reference is made to the experimental gas-compression lead-sheathed cable in Detroit, in which one section of cable had holes punched in the sheath every 25 feet. I agree that this particular construction was stable during the period of the experimental operation, but it was of course not then a compression cable because there was substantially free access of gas to all parts of the cable. With a single hole, however, such as might occur and be undetected in a 30 or 40 year operating life, it seems to me then that two things are evident—first, the cable adjacent to a hole in the sheath or joint covering would immediately lose its compression characteristic. More important, however, portions of cable remote from the break would ultimately acquire an indeterminate pressure characteristic. High unbalanced internal pressure of 100 pounds per square inch or more during heavy load periods could lead to pronounced longitudinal migration of the impregnant in the direction of the break, at which point there would of course be no pressure differential. It appears that on the cooling cycle, with lower temperatures and viscosities, the expelled saturant would only be partially replaced by the pressure medium.

When an undetectable break in the cable sheath or joint covering could change the initial cable characteristics so much that the compression characteristic would be lost, and since the addition of the polyethylene sheath apparently does not eliminate any of the usual installation precautions, it appears to be not at all certain that the extra complications of the sheath are warranted.

G. B. Shanklin (General Electric Company, Schenectady, N. Y.): The paper by McCormack, Hatcher and their collaborators describes in a very interesting way the polyethylene-sheathed compression-type pipe cable that has recently been installed on Long Island. I will confine my comments to Wyatt's section of this paper.

Wyatt gives a very concise outline of the basic principles of the compression-type cable system. Briefly, this type of system consists of two separate compartments which for convenience will be termed the cable space and the pipe space. These compartments are completely and permanently separated from each other by an oil and gas-tight impervious cover on the cable and joints. All space inside this covering not occupied by copper and paper is completely impregnated with a noncompressible liquid oil or compound. The pipe space is filled with a fluid pressure medium, either oil or gas. The separator between these two spaces acts as a diaphragm, and pressure is transmitted to the cable space through this diaphragm and from the pressure medium. To perform correctly during temperature cycles the cable space must be completely filled with an incompressible liquid and this must have a sufficiently low viscosity to flow radially and fill up all shrinkage voids as fast as they are formed. The restriction to this flow is so high that shrinkage voids cannot be filled up with sufficient speed if any of the filling compound in the cable space is accidentally lost and is not immediately replaced by a similar incompressible liquid.

From the foregoing it is obvious that the principle of the compression system is based on permanent tightness of the diaphragm separator, and if this is lacking the compression principle is lost.

Assume that a restricted leak occurs in the separator. Some of the compound in the cable space will be forced out through this leak during periods of increasing temperature. If the pressure medium is oil, this will be immediately replaced during cooling periods and there will be no void formation or loss of pressure control. This replacing oil, however, must be completely free of impurities and have an insulating value equal to that of the compound it replaces. If the pressure medium is gas there will be no replacement of incompressible liquid, and gas-filled voids will form in near proximity to the leak. This gas under pressure will be rapidly absorbed by the cable insulation, and pressure control will soon be lost in these voids because gas cannot enter the restricted leak as fast as it is absorbed by the insulation. The net result is that after a period of time low-pressure voids can exist and there will be a possibility of ionization at these points, which can travel for some distance beyond the leak. If any impurities exist in the gas-pressure medium, they will enter the leak and tend to concentrate in the insulation. Plainly, with the compression system complete tightness and imperviousness of the diaphragm separator is necessary.

Experience has shown that this can be obtained with lead sheath and metal sleeves over the joints when great care is taken in the construction work. There is a serious question whether the same permanently impervious construction can be obtained with any form of organic covering. This is particularly true at the hand-wrapped seals between the cable covering and the joint covering. Experience with such hand-wrapped seals has never indicated that permanent tightness can be obtained under pressure cycles.

Considering all these things we believe that no attempt should be made to follow the compression principle with an organic covering. It is better to leave the joints open and allow free entrance of the pressure medium into the cable ends by use of pervious joint wrappings. When oil is used as a pressure medium, any displaced compound from the cable will be immediately replaced and no void formation will occur. It is obvious that the Long Island installation is safe in this respect because oil was used as a pressure medium in the pipe and every care was taken to completely remove impurities.

When gas is used as a pressure medium, however, the behavior is quite different from that of the compression system at a point of leakage as described previously. The gas can freely enter the cable ends and will be absorbed up to the saturation point by the insulation. Complete saturation throughout the cable run will be reached in a relatively short time and any voids that form in the meantime due to displacement of the compound will be accessible to full pressure adjacent to these feeder joints. After complete saturation is reached throughout, any voids that tend to form at any location will be maintained under full gas pressure. Obviously also there will be very little loss of surplus compound from the cable because of the covering. A number of long-time load cycle tests have proved that even without this covering there is not a sufficient loss of compound to affect ionization voltage stability, the compound being held in place in the high stress field by capillary and electrostatic attraction.

We accordingly believe that a true oil-filled or gas-filled pipe cable system has many advantages over a compression system when an organic covering is used instead of a metal covering.

Guy N. Everest (The Okonite Company, Passaic, N. J.): The authors' paper is very interesting and the following comments will perhaps bring out the need for more data which are lacking in the paper.

It is pointed out that the first step in simplification was taken in 1940 at Detroit. Perhaps it would be better to say that the first Oilostatic cable installation in 1932 was the initial step to prove a new technique in cable systems. Elimination of ducts and lead sheath was the first simplification.

It is pointed out that effects of rust, mud and moisture, and so forth, which may exist under field conditions as well as difficulties of pulling unsheathed cable in wet weather, led to a nonmetallic sheathed cable design. Anyone who knows field conditions will agree that none of these impurities are desirable regardless of the cable design, nor does anyone know if the polyethylene sheath will still be in existence five years or so from initial installation date. If it is not, then the cable will be just as much exposed as if it had no sheath on it. Secondly, if the sheath is not present five years or so from installation date, why go to the expense of installing it. Nonsheathed cables have proved themselves in pipe installations. Lead sheaths can be removed at a far smaller cost at time of installation than the polyethylene sheath can be supplied.

Means can be used to cover up cable pulling operations regardless of type of outer protective coverings.

The remark about the cable which was tested in Detroit and whose sheath was punched with holes seems to indicate no sheath is required and certainly the oilostatic installations have proved this.

The discussion disagrees with the theory that long skid wires reduce coefficient of friction. We obtain 0.24–0.27 on the short-lay skid wires, and we are of the opinion that the inner surface of the pipe is more of a controlling feature than the lay of the wires.

It seems that a lot of information is given about this compression cable at elevated temperatures, and with load cycles, however, there is a definite lack of data about this cable's behavior under cold conditions such as exist at the ends of the circuits. Are there any data available to show that ionization does not take place at 0 degrees Fahrenheit, that the polyethylene sheath is responsive at low temperatures, and that it will function correctly?

It will be interesting to follow the operating experience of the pressure tubes in the potheads because so far none have been in service.

The paper is further written proof of the feasibility and practical aspects of pipe-type cables. It would be interesting if some installation manhour figures were available, broken down into the various operations covering the installations as well as the overall cost of the installation. Engineers are interested in this information.

Wyatt in his reply to discussions said that 115 miles of compression cable have been in service for many years and none of the expected troubles put forth in the discussion have happened. However, Wyatt did not go further and explain that lead sheaths were used in all these. Now he claims some hope for his plastic sheathed cable. There is no service experience and it has to be obtained in the next few years.

Dr. Wilhelm Vogel (University of Cologne, Cologne-Mulheim, Germany): As one who, next to Hochstadter, was perhaps closest associated with the development of the compression cable, may I be permitted to add a few remarks to the paper. First, I want to express my satisfaction that Wyatt, Del Mar and their co-workers succeeded in overcoming the last deficiencies still present in the European installations of this type of cable, whereby it became competitive for all pressures and applications with the hitherto most generally used high voltage cable, the oil-filled cable, and may eventually surpass it.

To the history of the compression cable and of its first installations I might contribute the following remarks. After Hochstadter established in his original European researches the correctness of his fundamental idea that ionization phenomena in the insulation may be suppressed through the application of mechanical pressure over a flexible impermeable membrane, he turned to us[1] among others with the request that we cooperate in the technical development of the system. Thereupon we established the fact that an increase of the pressure over eight atmospheres (100 pounds per square inch) resulted in an increase of the steady-state breakdown strength to about 40,000 volts per millimeter (1,000 volts per mil). This put the economics of the new system on a firm basis because the reduction in the cost of insulation and conductor offset the additional cost of the jacket carrying the high pressure facilities. Thereafter I established that round cable cross-section is unsatisfactory for continuous operation and introduced the triangular form of the *SO* cable and later the oval-shaped single-phase conductors. Likewise, I introduced the steel pipe against the many conservative opinions of manufacturers and users, as the most advantageous carrier of the pressure medium. Cables in steel pipes were unknown conceptions for the European; and it also took part of the business out of the hands of the cable fabricators, yet they could not prevent the victory of the steel pipe. All our pressure-cable installations on the Continent are in pipes, while the English, scared by the difficulties encountered on the first installation with defective corrosion protection of the pipe, returned to armored lead as the pressure carrier. The first installation on the Continent was made at Muldenstein for the German Federal Railroad. Then followed installations in Scandinavia, whereafter German authorities, too, became more and more interested in the new system, not only because of its technical advantages and safety against aerial attacks, and sabotage, but also because of its minimum use of lead.

The task at the experimental installation at Arnheim was to develop a system capable of transmitting 100,000 kva at a normal voltage of 150,000 volts with the restriction, that in case of trouble reserve facilities must be available. While in all other systems a fourth single-phase cable was considered sufficient, we could offer for practically the same price two complete pressure-cable systems for each 100,000 kva. Here we had to employ the most stringent care with regard to the dimensioning of the conductor and the insulation, because the test conditions were extraordinarily hard; 10 per cent overload and 173 per cent over-voltage for more than 100 heating cycles. Here, too, we used a corrosion protective sheath containing quartz in order to minimize undesirable heat resistance.

As we succeeded by technical means to increase the life expectancy of the lead sheath considerably, it became clear to us that in this instance too, we had to break with traditions of cable technology the same way as we did eventfully in the case of the steel pipe. Many experiments were made among others, with sheaths of polyvinylchloride, which were not quite satisfactory. During the war, and even now, it is difficult to obtain more appropriate materials.

The use of polyethylene in the United States is a step in the right direction. The same is true in respect to abandoning the original system of cabling the three phases. The latter at the same time reduces the difficulties connected with the linear expansion of the cable in the pipe sufficiently, to forego the need for the heavy anchoring which we found necessary. Parallel to this is the simplification of the sleeves. On the other hand, I believe we had a priority in the development of terminals. With the co-operation of a German porcelain manufacturer[2] we were able to obtain pressure-tight porcelain insulators which stood up under severe tests, which consisted of heating cycles in water between +10 and +75 degrees

centigrade and under triple working pressure. These are still in actual operation.

R. J. Wiseman (The Okonite Company, Passaic, N. J.): I wish to commend the authors of the paper for its thoroughness in presenting the theory and design of the system and the method used in installation. Some of the design features, such as the skid wire, safety head, and discharge tank on the semistop joint, and two manhole openings were developed by the Okonite-Callender Cable Company as a part of the development of the Oilostatic system.

Reference is made to the elimination of the use of a lead sheath on shipping of the cable and thereby an improvement in installation. The only improvement is the elimination of the manpower in removing the lead. When the Oilostatic cable system was developed, we were not certain what protection was necessary to take on shipping of the cable. To give maximum protection, we used a thin-lead sheath which can be easily removed. This has proved quite successful. We soon also realized that it would be desirable if a method were found to ship the cables without lead sheath. This has been accomplished so that today we are prepared to do so. However, do not get the impression because the cable is shipped nonleaded that it can be installed in all kinds of weather, rainy or dry. This applies to the compression-type, high-pressure gas, or Oilostatic cables. None of them are better off than the others in this respect, except those that use oil as the pressure medium. If moisture gets on the surface of the cable and is not removed during the evacuating of the pipe prior to setting up the pressure medium, the oil flowing into the pipe will wash off the surface moisture, if present, and as oil is flushed out, the moisture will be removed. This will not take place in gas filling. We have checked oil removed during the filling operation for dielectric strength and have obtained values over 30 kv, in many cases 42 kv.

There is nothing harmful in allowing the nonjacketed cable to come in contact with the atmosphere or in contact with the inside of the pipe. The insulation is covered with a shielding tape, and all who are acquainted with cable operation know that a shielding tape is a very good barrier to moisture penetration. Also, there is wrapped over the shielding tape a "*D*" wire or skid wire as specified in the paper. This skid wire raises the cable off the pipe but helps in getting a good grounding contact, provides a space to obtain flow of oil around the cable, and has helped in reducing the coefficient of friction.

Referring again to the *D* wire, we have used one and two *D* armor wires on installations, and we also get a coefficient of friction of 0.24–0.27, just as good as reported in this paper for three wires. The number of wires and their length of lay have no influence on the pulling friction.

Long length of sections is not solely applicable to the compression cable system. When we first introduced the Oilostatic system in 1932, we recommended at least 2,000-foot lengths, and if straight pulls, 2,500 feet. We soon found out that usually these lengths are not attainable, and a 1,500-foot length more common, with many even shorter. It is desirable to have as long lengths as possible in order to reduce the number of joints, but do not expect that only 2,500-foot lengths or higher will be used. There will be many shorter lengths, due to bends and obstructions.

Wyatt in his history of the development of the compression cable refers to the investigation made by Callender's Cable and Construction Company. It should also be stated that they studied the self-contained high pressure gas cable both in their own laboratory and also at Arnhem, Holland, with complete success in both cases for cable, joints, and terminals, no indication of increase in power factor or ionization after several years of testing.

Let us not get the impression from the paragraph on working stress of Wyatt's section that for the present this design, any more than any of the other designs of high-voltage cable, will be operated at a maximum stress of 375 volts per mil. Tests we have made on the Oilostatic design indicate very high working stresses, but we are held back from using them because of the limitations in the impulse strength of the insulation. When we know more about the effect of pressure on impulse strength, we can decide how far we can go in reducing insulation thickness.

The electrical tests reported by Del Mar and Merrell are comparable to what we have obtained on the Oilostatic cable system.

The installation of the system as written by Hatcher and DeTurk is quite complete. We note that the entire line was filled with oil at one time. This is possible for all designs using oil as the pressure medium. However, we feel that it is better to have semistop joints frequently located so that when the cables are jointed between them and the barrier plates located, it is possible to evacuate this section and fill with oil while other installation operations are taking place. This helps to reduce the time of installation and also because of the short lengths to evacuate, higher vacuum can be obtained. We would like to commend the authors for the completeness with which they have presented the subject.

F. W. Main (Enfield Cables Limited, Brimsdown, Middlesex, England): I am glad to have the privilege of contributing to the discussion on this compression cable group of papers, having done so much in the early days of development.

The thoroughness of the investigations in development, design and manufacture of compression cable with polyethylene-diaphragm sheath as detailed in the group of papers is to be admired and it has brought its reward in the amount of such cable being installed for commercial use.

The compression cable still leads supertension cables in high-safety factor and this has never been seriously challenged, but only the necessity for it!

It is interesting and satisfactory to learn that engineers in the United States have done so much to prove and then adopt the principles of the compression cable as detailed briefly in the first paper, aided by reproduced curves referring to the early British investigations and developments.

The authors have made adjustments to European designs to meet prevailing conditions in the United States.

In some types of supertension cables employing gas under pressure, so-called harmless gaseous ionization is acknowledged and tolerated, but in the compression cable I must confirm the authors' statement that ionization is entirely suppressed.

In the United States you have cables other than the compression cable in pipes but, as correctly pointed out by Wyatt, no costly cleaning of inside surface of pipe or special treatment is necessary for housing the compression cable as the pressure medium does not contact the cable insulation—it is not part of the active dielectric.

We cannot agree with the statement that the European compression cable design is clumsy, it may be liberal in reinforcement precautions and materials but 10 years of successful service of the pipe-line cable in Great Britain and eight years of service of self-contained cable have justified any apparent conservatism in early designs. As far as complicated joints are concerned we would refer to Figure 1 of the discussion, illustrating the 132-kv joint installed in England. Comments are unnecessary. We consider the American joint as shown to be more complicated than ours.

Figure 1. 132-kv joint installed in England

In Britain an alternative for lead as a pressure conveyor diaphragm to the dielectric has been sought, but the plastic field has not been acceptable due to the inherent porosity and in the case of polyethylene, swelling of the material when in contact with oil at elevated temperatures, which effect we have confirmed. We would like to know whether the polyethylene available in Great Britain is similar to that obtained in the United States.

It will be interesting to watch these installations in the United States to see whether, with the precautions taken, the anticipated length of life of the polyethylene inner sheath is justified; we consider there is a greater chance when using oil as the pressure medium than when employing nitrogen gas. We do not favour oil as the pressure medium as it involves plant to deal with changes of volume and movement as load varies in the cable and the effects of changes of gradients, whereas, the use of gas calls for no accessories.

We have not found it necessary to use cathodic protection as the Enfield Sandwich is sufficient.

As we use stabilised insulators our porcelains are single shedded.

We note that you are successful in the States in drawing three heavy cables into one pipe.

A. L. McKean (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): The 3-phase laboratory replica of the 138-kv tie line has been opened for inspection after load-cycling under voltage for one year. A total of 127 load cycles, each of 48-hours duration, have been completed, 60 cycles to 70 degrees centigrade, 67 cycles to 85 degrees centigrade conductor, average temperature measured by change of copper resistance. Due to uneven circulation of air and the cooling effects of the copper risers, hot-spot cable temperatures were from 5 to 10 degrees higher than average.

The aged cable, including terminals, proved to be in excellent condition, appearing like new. Visual inspection revealed no signs of deterioration. This was further substantiated by comparison of radial power factor tests at 100 degrees centigrade, results after test being identical with those on new cable.

Careful visual examination of the polyethylene sheath after test revealed no adverse effects from the load-cycling. Tensile test results, equivalent to those of newly extruded sheath, confirmed the visual inspection.

The electrical behavior of the cable during all phases of the load-cycle test was essentially stable.

Normal load-cycle testing to 70 degrees centigrade did not affect cable power factor. Power factor, at both room temperature and 70 degrees centigrade conductor, remained constant at 0.31 per cent, ionization factor at 0.01.

Likewise, controlled overload tests to 85 degrees centigrade did not affect stability. After completion of 67 overload cycles at 100 kv to ground, cable power factor and ionization were unchanged. The radial power factor tests at 100 degrees centigrade, mentioned before, confirm these findings.

Load-cycle testing at zero gauge pressure during 5-load cycles, at various intervals throughout the test period, demonstrated the system's stability under "emergency" conditions. The longest continuous-zero-pressure operating period was for 96 hours, 2-load cycles.

It was also shown that sudden removal of pressure and full load, simultaneously, did not immediately result in ionization; instead ionization increased slowly to a maximum upon complete cooling of the cable. Apparently, the initial rapid cooling of the conductor does not induce immediate ionization because of the reversible elasticity of the oval cable structure. Moreover, restoration of load, without pressure, reduces ionization, gradually, to the original negligible value.

Reapplication of pressure immediately eliminates ionization and restores cable power factor to its normal low value.

Ovality Ratio and Expansion

W. A. Del Mar and **E. J. Merrell** (Phelps Dodge Copper Products Company, Yonkers, N. Y.): Atkinson's attention is called to the fact that the test results plotted in Figure 6 of the paper are for cable without external pressure. When a pressure of 200 pounds per square inch is applied, the long sides of the oval flatten and the ovality ratio drops to about 0.85, as indicated in Figure 5 of the paper. This allows a greater change of ovality than that calculated by Atkinson but is not sufficient to accomodate all the expansion. No compression cables, however, are designed with that in view. The designs are made by balancing the expansion of copper, paper, oil and sheath against the increase in volume resulting from compression of the paper, change of ovality ratio and the elastic stretch of the sheath to the extent allowed by the slight give of the bronze tapes. No allowance is made for poor impregnation, as the impregnation is necessarily very thorough in order to meet the stringent ionization test.

Flow of Polyethylene

Atkinson asks if the cyclical changes of pressure will cause a flow of polyethylene from the long axis to the short axis, due to the greater pressure at the former points. The answer is a definite "no". In none of our many load cycle tests has any such change occurred. In fact, the sheath is always a trifle thicker on the long axis than on the short axis.

Joints

Halperin asks about the polyethylene seal on the joints. Load cycle tests have shown this to be satisfactory under working conditions, provided that the internal pressure is not excessive, that is, much beyond the amounts to be expected in service. Hatcher's discussion gives further data on this point.

Impulse Strength

McGrath believes that the small radius of the oval cable has the effect of reducing the impulse strength and cites the "maximum stress" theory in support of this contention. This theory is a useful one if used within its limitations, but it should not be used indiscriminately. The idea that impulse strength is a function of maximum stress, derives principally from a paper by L. I. Komives.[1] Tables I and II of that paper cite 38 impulse tests on ionization-free cables of American manufacture and give the calculated maximum stresses, which I have averaged for each conductor size, as follows:

Conductor Radius Mils	Calculated Maximum Stress Volts Per Mil (Average Values for Each Conductor Size)
945	2,840
542	3,350
515	3,296
514	2,540*
514	3,290
290	3,118

* Cited as "very irregular".

It will be seen at once that the maximum stress theory seems to act in reverse, so to speak, the cables with the smaller conductors failing at by far the greater "maximum stress". This is not a new idea; it has been known for years that if two cables are designed for equal "maximum stress", one with a small conductor and thick insulation and the other with a large conductor and thin insulation, the one with the small conductor will have far higher breakdown voltage.[2,3,4] In other words, the maximum stress theory, when applied to breakdown voltages does not agree with fact, if conductor radius is taken as the variable. I therefore cannot give much weight to McGrath's criticism of the oval-shaped conductor. Perhaps the reason why the maximum stress formula is used by McGrath is that in cables of non-circular cross-section, failure usually occurs at a region of small radius. This fact is recognized but it does not prove the correctness of the logarithmic formula for variable conductor sizes.

The maximum stress appears to be a useful guide, however, if insulation thickness is the variable. This may be seen from Komives'[1] Table II where data are given for two cables of equal conductor radius dut unequal insulation thickness. These data are as follows:

Conductor Radius Mils	Insulation Thickness Mils	Average Stress (Average of All of Each Type)	Maximum Stress (Average of All of Each Type)
945	315	1,634	2,440
945	500	1,386	2,240
Difference		248	200
Per Cent Difference		15.2	8.3

The maximum stress, in this case, appears to advantage as a guide to breakdown voltage. McGrath, looking at Figure 7 in the paper concluded that I accept the maximum stress theory in toto. He failed to note that the tests recorded therein were all on cables of equal conductor size.

Insulation failure begins, of course, where the stress is greatest. The whole point is that the conventional logarithmic formula does not give correct comparative stresses in cables of different designs. A study of

W. D. A. Peaslee's discussion,[5] and P. L. Hoover's paper[6] may afford the clue to these discrepances.

While the use of high-density high-elasticity paper for the outside layers of insulation gives lower impulse strength than when such paper is used for the inside layers, the ability of the cable to operate without pressure is superior with the former construction, due to the elastic tightness with which the interior layers of insulation are held. It is a matter of judgment, based on local conditions, which of these factors should predominate.

The conclusion which I draw is that there is nothing about the compression cable design which puts it at a disadvantage in the matter of impulse strength.

Loss in Skid-Wires

We have made a 3-phase set-up in our laboratory which is a short replica of the Long Island tie line and have made some tests to check McGrath's figures on losses in skid-wires. Of course we could not insert an ordinary ammeter in the skid-wire circuit because its high impedance would cut down the current in a circuit of such low resistance. Instead we have used a Ferranti clamp-on ammeter and checked its effect by means of a high-amplification oscilloscope calibrated as a voltmeter. This revealed that when the ammeter was clamped on, there was a negligible change of current.

McGrath takes the sheath loss in an equivalent group of lead sheathed cables with sheaths short-circuited, as his basis of comparison. We estimate this as 315 watts per 1,000 feet of each conductor.

We made our tests first with the skid-wires in natural contact with one another and with the pipe as they actually are in the tie line and then with the skid-wires insulated from the bronze-binder tapes and from one another. In the latter case the current varied between 9 and 10 amperes per skid-wire with 400 amperes in the main conductors. McGrath's estimate that the loss would be between 50 and 75 per cent of that in the short-circuited lead sheaths, means a loss of 157 to 236 watts per 1,000 feet per phase, which is equivalent to a current of 7 to 9 amperes per skid wire. This is in fair agreement with our measured 9 to 10 amperes.

However, when the skid wires were uninsulated and in their natural electrical contacts, the rms value of the current in each of them was only 3.7 amperes. With this current the loss would be 41 watts per 1,000 feet of cable instead of McGrath's 157 to 236 watts.

Expressed as a percentage of the line loss, this is less than 0.7 per cent and expressed as a percentage of the loss in short-circuited lead sheaths, 13 per cent.

While the loss may be somewhat less with short-lay skid-wire, it is quite negligible on cable of this size, and subordinate to the advantages of a long lay. For large sizes, skid wires of metal of higher resistivity may be found desirable in order to retain the advantages of long lay.

Kenneth S. Wyatt (Phelps-Dodge Copper Products Corporation, Yonkers, N. Y.): Our description of this simple and relatively fool-proof pipe cable system has come in for considerable criticism at the hands of Pettee, Atkinson, McGrath, Wiseman and Everest. Del Mar, in his discussion, has answered several important criticisms by actual experimental work. In answering the remainder, I wish to focus sharply on a number of hard facts. In the first place, installations of the compression cable with lead sheath abroad, from 66 to 120 kv, now total about 100 miles. They are all giving good service, the first one in London for sixteen years. There are now fourteen miles of the simplified system with plastic sheath operating satisfactorily in this country, and there will be considerably more before the end of 1948. This means that in both operating mileage and mile-years the compression cable is second only to the Pirelli oil-filled system. None of our critics can point to a record like that. However, I fully agree that all possibilities of trouble should be considered even though mature deliberation shows them to be purely imaginary.

When the cable was equipped with a continuous sheath and was in effect a factory-sealed unit, why did we clean and coat the inside of the pipe and take precautions against the entry of moist air on the Long Island installation? Simply because it was a first installation in this country and the engineers concerned considered this a prudent move. None of the pipe abroad was freed from rust nor were any elaborate precautions of any kind taken because the pipe was considered to be merely a duct. We do not clean the inside of a concrete duct bank for oil-filled cables. As a matter of fact, on our installation of 138-kv compression cable at Milwaukee, it was agreed to make one pull a day regardless of weather. The cable was pulled with scanty tarpaulin cover in one case in heavy rain, in others at temperatures as low as −15 degrees centigrade, with 12 inches of snow on the ground, and, in general, under difficult field conditions. We, of course, require that the pipe line be evacuated until any moisture taken in with the cable is removed.

Thus, it could hardly be said that field operations with this cable are at all critical. Contrast the experience at Philadelphia, in 1947, where between May first and August first they had 78 days of rain, during which there was not any cable stripped of sheath and pulled into the pipe, and as a result the labor stand-by time increased the cost of the installation significantly.

In the oral discussion, our continuously sheathed cable was called an anachronism and an atavism. They said we should strip off the sheath. I well recall a speaker saying last year, in an Edison Electric Institute meeting devoted to finding ways of reducing underground cable costs, that since some manufacturers stripped the sheath from the cable before pulling into the pipe and filling with oil, why not go one step farther; instead of putting on a sheath only to be stripped off again, why not just insulate the cable with dry paper at the factory, pull into the pipe, and dry, evacuate and oil-impregnate in the field? Other discussors soon brought out the point that the field is the last place to do such a delicate job, as conditions of humidity, rain and mud are beyond control. The costs would be increased enormously and that for a high quality and economical job every operation possible should be done in the factory where conditions can be controlled. We agree with this view, and we strongly believe in sealing the cable at the factory with a continuous sheath so that we are not dependent on the vagaries of field conditions.

Pettee states that his sheath of polyethylene and metal tapes, which he says keeps the air and moisture out during shipment, but freely lets the nitrogen or oil in when it is installed in the pipe (by some subtle mechanism beyond my comprehension), is more economical. With such taped-sheath cables very special reels are employed which represent an appreciable additional expense. The experience to date with such a taped sheath is that during shipment most of the cable lengths leak several gallons of oil. The present standard reply to that is, "What does a leakage of a few gallons of oil matter in a 2,000 foot length of cable?" I think it matters a great deal in a cable at 100 kv or over, because a few gallons of air must have leaked in where the oil leaked out. This means potential ionization, and that means, in turn, a weakening of the cable. It is now over twenty years since I started taking apart extra high-voltage cables that had deteriorated and failed at Detroit, and the whole of this experience is against such indeterminate improvisations as the taped sheath.

Halperin and others request more information on the permanency of the polyethylene sheath. Quite apart from the very considerable engineering advantages of a polyethylene sheath, that is, its light weight making for long-pulling lengths and elimination of two out of three manholes and its nonconducting properties eliminating sheath losses, polyethylene has other important advantages over lead as a sheathing material. Although it has a technical softening point at about 110 degrees centigrade, it is extruded on the cable at 185 to 190 degrees centigrade, a temperature not far below the extrusion temperature of lead. Polyethylene has an elongation of over 400 per cent in sheet form, somewhat less in sheath form, whereas lead will split or crack with only a small fraction of this elongation. There is a complete absence of oxide seams such as have been found with lead. Polyethylene does not increase the power factor of the insulation layers in contact with it as does lead. It is a homogeneous material without plasticizers or fillers; it is crystalline and will not cold flow at loadings below the cold-drawn point at temperatures up to approximately 90 degrees centigrade.

Polyethylene is a tough leathery material which should withstand millions of cycles of flexing without rupture. For example, the polyethylene insulation of coaxial cable up to $^7/_8$-inch diameter, when subjected to

twist tests consisting of 360 degree twists in 17 feet, withstood over 400,000 cycles without failure, termination of the test always being due to breaking of the copper. In another test strips of polyethylene sheath taken from the Long Island cable sheath were flexed in the University of Illinois lead-sheath tester. Whereas copper-bearing lead usually fails in about 7,000 cycles, polyethylene so far appears unchanged after 298,000 cycles. For these reasons the polyethylene sheath, reinforced with bronze tapes so as to have a bursting strength of over 500 pounds per square inch, is, in our experience, far more durable than a lead sheath.

Although polyethylene has the highest impermeability of any commercial organic plastic material, it will pass moisture vapor at an extremely low rate over a long period of time if a moisture-hungry material is present on the other side. Polyethylene itself does not absorb water (less than 0.02 per cent by weight). However, we believe a polyethylene sheathed paper cable if submerged in water would operate satisfactorily for 10 or 15 years. In the steel pipe, moisture vapor is evacuated before filling with the 200 pound pressure medium.

All that we know physically and chemically about polyethylene leads to the conclusion that it should be absolutely permanent. It consists of alifatic carbon and hydrogen chains, very similar to paraffin wax, but with very long chains with some cross-linkage to give it toughness. Paraffin wax, as is well known, is chemically inert and does not oxidize or change with time. Polyethylene communication cables laid under the sea have now given nearly 10 years of satisfactory service. In consequence it has almost entirely replaced guttapercha and rubber for this purpose, and installations of undersea polyethylene cable represent very substantial investments. More recently polyethylene is being used to replace lead as a sheath for telephone cable on a mass production basis. In this case a thin metal covering, perhaps 20 mils in thickness, over the polyethylene serves to prevent the diffusion of moisture vapor through the polyethylene. This activity has necessitated the building of new polyethylene plants in addition to new cable production facilities. It represents an investment of many millions of dollars, which has been based on investigations over many years by an extensive and capable research organization, of world-wide reputation. Polyethylene is thus regarded by the best technical opinion in several countries as an absolutely permanent sheathing material.

In the case of power cables there is the complication of impregnating oil in contact with the sheath. Polyethylene swells in oil at temperatures above 65 degrees centigrade, although the effect is reduced the higher the viscosity of the oil, and the higher the viscosity index. A metal-reinforced polyethylene sheath does not swell in oil at 70 degrees centigrade, nor does the tensile strength diminish. Just as rubber cannot absorb water when restrained to prevent swelling, so it appears that polyethylene when restrained cannot absorb oil. Used on experimental cables it has been completely satisfactory. Two lengths of 138-kv cable identical with that used on the Long Island line were each installed in a vertical pipe 80 feet high, one at atmospheric pressure external to the sheath, and the other at 200 pounds per square inch nitrogen. The ends were sealed. The cables have been given one load cycle a day to 45 degrees centigrade above ambient. The two cables are behaving perfectly normally after eleven months, there being neither leakage of oil through the sheath nor permanent change of ovality. Likewise, in all our work load-cycling compression cable with reinforced polyethylene sheath in pipes filled with oil or with gas we have never observed any damage to the sheath in the form of swelling, tears, or pinholes, even though these tests have run 200 and 300 load cycles to 85 and 90 degrees centigrade copper. Finally, we must point out that the present allowable copper temperature for 138 kv cable is 70 degrees centigrade, which corresponds to a sheath temperature of 51 degrees centigrade. At this temperature polyethylene does not swell in oil even if not restrained with bronze tapes.

We believe that if an oil-compression cable is operated continuously at 70 degrees centigrade sheath, which corresponds to a copper temperature of 100 degrees centigrade, the sheath is safe. The gas-compression cable we believe is safe to 90 degrees centigrade sheath, corresponding to a copper temperature of 125 degrees. We hope this will satisfy Halperin. However, we are not satisfied that oil-paper insulation on 138-kv cables is safe at 100 degrees centigrade or over, since at this temperature we are approaching very closely the thermal instability point of the paper insulation. We think it sounder practice to use a larger conductor size.

A warning should be given regarding statements as to the properties of polyethylene. There are many grades, according to molecular weight. A medium molecular weight grade is a soft paste-like material. Then there are several types of polyethylene; the product of some manufacturers swells more in oil than that of others; those that swell least have a greater degree of cross-linkage than others. We are careful to employ a high molecular weight polyethylene which exhibits a high degree of cross-linkage.

Experience is important in extruding polyethylene sheath. It is of the highest importance to eliminate strains. This means close temperature control. We have extruded about sixty miles of polyethylene sheath on single-core cable, yet we have never seen a pinhole; and all has been substantially free from strain. Accordingly, if a statement were made to us that a polyethylene sheath has not passed certain tests, we should interpret it to mean that the wrong type or grade of polyethylene was used, or the extrusion equipment was inadequate, or that the manufacturer of the sheath lacked the necessary experience.

Utility engineers associated with the installation of both gas- and oil-compression cables have expressed the opinion that if all the dire predictions came true and the plastic sheath disappeared completely 15 minutes, or 15 years after installation, the cable would be at least as good as sheathless or taped-sheath cables in pipes filled with gas or oil under high pressure from that time on; and prior to the disappearance of the sheath the cables would be much better because installation would have been simplified and the initial high factor of safety would have been maintained unimpaired by deterioration up to that point. On our part we can only restate our conviction, based on seven years experience with polyethylene and three years of experimental work with polyethylene-sheathed compression cable, that the sheath will have as long a life as our steel-pipe system. As to that, we doubt whether any electrical engineers who have now graduated will live long enough to find out the answer.

Atkinson raises the question as to the adequacy of the oval form in compensating for oil expansion. Experimentally, it has been conclusively demonstrated many times during the last twenty-two years, both here and abroad, that the oval does not become circular even under maximum permissible overload. The stroke on the minor axis has been carefully measured by capacitor and other methods. Has Atkinson forgotten how carefully we went over this ground in 1939–1940 at the time he became licensed to make this cable? And has he forgotten his own experiments dated March 22, 1940, just prior to his making the Detroit experimental compression cable, which showed that the most thoroughly impregnated cable he could make exhibited a compressibility at 200 pounds per square inch external pressure of approximately 1 per cent of the insulation volume? However, we are pleased he has raised this point, as it will have interest for many cable engineers.

All oil-paper insulation exhibits some compressibility due, it is believed, to minute cells in the paper which are not filled with oil. Del Mar has given a fuller discussion of the ovality compensating action.

Discussions by Shanklin always command our respect because for twenty years he has been a chief advocate of maintaining oil-paper insulation completely filled with oil to obtain high dielectric strength and high factor of safety in extra high voltage cable. In his 1942 discussion of the Faucett, Komives, Collins and Atkinson paper,[1] Shanklin states,

"Experience . . . . . indicates that it is not possible to avoid occasional leaks in the (lead) sheath envelope".[1]

Six years later he now says,

"Experience has shown that complete tightness and imperviousness of the separator can be obtained with lead sheath and metal sleeves over the joints when great care is taken in the construction work."

Obviously the continuing satisfactory service of great mileages of gas-compression cable (lead sheath) abroad has caused Shanklin to modify his earlier opinion. But now his worry is transferred from the lead sheath to the polyethylene sheath, which is understandable. He states the oil-compression cable is safe. The gas-compression cable worries him because if a restricted leak in the sheath occurs,

"some of the compound in the cable space will be forced out through this leak."

Later he answers this doubt himself by pointing out,

"Obviously there will be little loss of surplus compound from the cable because of the covering. A number of load cycle tests have proved that even without this covering, there is not a sufficient loss of compound to affect ionization voltage stability, the compound being held in place in the high stress field by capillary and electrostatic attraction."

Experimentally we know that a metal-

Figure 2. Effect of pressure on safety factor

reinforced lead sheath with three oil-paper tapes under the reinforcing tapes does not leak oil under load cycle conditions when a six-inch split in the lead sheath occurs at an oxide seam; nor is the cable harmed electrically. We attribute the absence of leakage more to the metal reinforcing and paper bedding tapes, and to the relatively balanced pressure across the sheath than to capillary and electrostatic attraction about which we are frankly skeptical. In England a 132-kv gas-compression pipe cable was load-cycled to 90 degrees centigrade copper for a year at a maximum stress in excess of 280 volts per mil. A load cycle without pressure indicated a small amount of ionization on the cooling cycle. Upon reapplication of pressure this ionization disappeared. Later, upon dismantling the installation, the longitudinal split in the lead sheath referred to before was discovered. Evidently the small amount of ionization without pressure was due to the entry of gas. This and other experimental evidence have led us to the conclusion that if the sheath of our compression cable is made reasonably tight, its high reliability characteristics will be maintained. The impressive service record supports that conclusion.

Shanklin is mistaken in supposing that the gas in the pipe can freely enter the cable ends. We have gone to some pains to prevent this happening. Gas pressure is communicated to the oil in the terminals by a compensator metal membrane. A gas-tight gland separates oil in the terminal from gas in the pipe. The compensator maintains a balanced 200 pounds per square inch pressure across this gland, and the differential across it at any time is not more than a few pounds.

The oil does not flow radially through the paper layers of an oval cable to any extent, as Shanklin points out. Rather, oil and paper distend outward as a unit on the minor axis. On the load cycle there is a tendency toward compression of the paper on the major axis and reduction of the oil film thickness, and vice versa on the minor axis. Accordingly, there is a slight movement of oil circumferentially in the interlayer spaces. On the cooling cycle this interlayer flow occurs in the opposite direction.

Everest requests data as to the cable's behavior at 0 degrees Fahrenheit at circuit ends. Polyethylene is flexible down to −70 or −80 degrees centigrade. As to the functioning of the compression cable principle at 0 degrees Fahrenheit, we refer him to the installations at Oslo, Norway, which has been operating without incident for fourteen years, and at Stettin, Germany, which has been operating satisfactorily for thirteen years.

Everest piles supposition upon supposition, assuming that, in time, the polyethylene sheath will disappear. We have presented evidence that it will not disappear. I am much more concerned about the rubber gaskets in his installations, where the steel joint sleeves are fastened to the pipe all along the line. It is well known that rubber contains accelerators, often sulfur and chlor-compounds, which cause it to age. However, we have not questioned the soundness or permanence of his system. If criticism is made sufficiently destructive, few modern engineering structures would escape some question as to permanency. For example, the rate of creep of steel under high pressures such as obtain at the base of our skyscrapers has raised criticism in some quarters. The only answer to such criticism is the same as we have given in connection with compression cable—look at the operating record.

Several discussors refer to the coefficient of friction as a function of the number and length of lay of the skid wires. Faucett, Komives, Collins and Atkinson,[1] in pulling 120-kv cable with oiled fabric cover at Detroit obtained a coefficient of 0.54. By using one D-shaped skid wire applied with a $1^1/_2$-inch lay on a cable of similar size, they later reduced this to 0.37.[3] At New Orleans, Bullard, Pettee and Rhodes,[4] increased the number of skid wires to two, and the lay to three inches, and thereby reduced the coefficient to 0.30. In the Long Island compression cable we simply used three wires and a lay of 12 inches and still further reduced the coefficient to the value given by Hatcher, namely, 0.24. However, other factors may modify these results, for example, if the pipe is a tight fit on the cable, in addition to the normal points of contact on the bottom of the pipe, the skid wires will be forced against the pipe on the top and sides; if the conductor is large, it will act as a strong spring, forcing the skid wire against the pipe at these points. Wiseman has had experience with such cases, and this may explain the contrary results.

In reply to McGrath, it is essential when using a 3-wire long-lay skid construction to apply the *D*-shaped wires tightly. Obviously, even if the skid wire were applied to our oval cable circumferentially without any lay, it would flex toward circular just as do the bronze reinforcing tapes. In going to a 12-inch lay, we had no thought in mind other than to reduce the coefficient of friction.

In the oral discussion we gladly gave credit to Wiseman for the skid wire idea, and only claimed an improvement in construction with three wires instead of one, and a lay of 12 inches, instead of $1^1/_2$ inches. Del Mar has since called my attention to an actual piece of the original 1931 pipe cable in London mounted on his laboratory wall, and this has a skid consisting of a rectangular steel strip $^1/_4$-inch wide applied with $3^1/_2$-inch lay. Hence we can now only give Wiseman credit for rounding off the edges.

These and other items appear to us to be details which should not distract us from the central facts, namely, Martin Hochstadter introduced the pipe-type high-pressure extra high voltage cable in London in 1931. He used a welded-steel pipe line protected against corrosion laid under the streets. Into this he pulled a sheathed cable. Then he filled the pipe at the ends with 200 pounds per square inch oil and in the main part of the line with 200 pounds per square inch nitrogen. Later Hugo Sonnenfeld proposed the same system, but with the sheath stripped off, and C. E. Bennett actually made such a system, limiting himself to oil as the pressure medium. The Sonnenfeld–Bennett modification had some justification in that the great weight of the lead made for short pulling lengths, more manholes, and in addition the lead resulted in serious sheath losses.

As Vogel aptly points out, to make the pipe cable a real success, it was not sufficient to break with tradition in the matter of the pipe alone; it was essential to break with the tradition of lead as a sheathing material, and to replace it with a light-weight tough and inert material, such as polyethylene.

Today with the advent of the plastic sheath, there is no engineering or economic reason for stripping the sheath from a cable—only commercial reasons.

But Wiseman has made a great contribution to pipe cable development in this country. He has spent over ten years in formalizing the current carrying capacity calculations of such cables, and in determining pipe cable constants. He has also investigated transient conditions in pipe cables, using the thermal transient calculator at Columbia University. Wiseman and Bennett worked out in a practical manner the oil-pressure and expansion system for oil-pipe cables. Their advocacy of the pipe system over long years did much to make it acceptable for American practice. The final proof of the practicability of buried pipe for high-pressure cable systems was the 7-mile 120-kv line in Detroit in 1941, which withstood successfully 200 pounds per square inch nitrogen pressure for six years without any leakage in pipe, and which was absolutely free from corrosion due to the use of a heavy well-tested pipe coating.

I am surprised at Everest questioning the terminal design, since he is using terminals of identical design and manufacture on his own 138-kv Oilostatic cable at Maspeth, Long Island, which is now in operation. The same design was used on the 138-kv San Antonio pipe cable which has been operating for several months. The same design is also being used for many other

pipe cable installations and the National Advisory Council for Aeronautics high pressure self-contained cable.

Halperin fears a 3-phase short. If this is going to occur anywhere, it will be at the joint. We can guard against this by use of a grounded-metal sleeve over each core. Today with fast-acting relays there would seem to be no excuse for a 3-phase short in a pipe system.

In reply to Vogel, the British are not "scared" of steel pipe. One reason for their cautiousness is the heavy penalties their courts may exact if cathodic protection on the pipe causes damage to nearby structures. Their crooked narrow streets require many bends of short radius. There is now a swing in thinking in Great Britain toward steel pipe construction, and it is probable more such lines will be put in in the near future. I believe the steel pipe duct for high pressure cables was first proposed by F. W. Main.

Halperin thinks the number of designs for extra high voltage cables is now excessive and some should be eliminated. It will require several years to crystallize opinion in favor of perhaps three or four designs. Certainly every cable engineer would prefer gas to oil as the pressure medium between cable and pipe because of absence of pressure differentials along the line resulting from sudden changes in load or due to profile, and because of absence of complicated joint accessories, pumping station and expansion reservoirs. On the other hand, he would prefer to have the paper insulation completely filled with oil so as to realize a high factor of safety against long-time breakdown. This combination of gas in the pipe for simplicity and 100 per cent oil-filled insulation for high safety factor can only be obtained by employing a continuous sheath over the insulation. If such a sheath is used, a means must be found for compensating for differential expansion of the oil. This may be done in a simple manner by making the cable oval in cross-section. When these three steps have been taken, you have a compression cable. The small extra cost of the sheath is justified many times over by the high-safety factor thus obtained, Figure 2 of the discussion, the permanency throughout life of this safety factor, and the savings in installation costs due to a moisture-proof sheath. One other important advantage accrues from this construction, that is, the ability to operate for 24 hours if pressure is lost. In special cases the pipe may be filled with oil. These advantages are so outstanding that we believe the compression cable system will have a permanent place among our standard cable types.

The system described, and other pipe systems, bear the creative stamp not only of the manufacturers, but also of the utility engineers. For example, the use of polyethylene sheath, the long-lay skid wires, and many other novel elements of design. It has required courage and foresight on the part of the utilities to embark on these new designs, and great credit is due them for the present progressive state of the art.

C. T. Hatcher (Consolidated Edison Company of New York, Inc., New York, N. Y.): Certain questions have been raised by the discussers of the paper pertaining to the justification for selecting the compression-type cable, and tests which justified the selection of this type of cable. The following discussion covers these questions.

Halperin questions the ability of existing circuit breakers to interrupt a possible phase-to-phase failure in the pipe. This type of failure has been considered and the circuit breakers on our system are of sufficient capacity to clear such a fault. In addition the relay settings are such that it is expected a fault will be cleared before it develops into a phase-to-phase fault. Halperin also questions the economy of a pipe-type system as compared to an oil-filled cable system on the basis that existing conduit systems could be used for an oil-filled cable system. Installation of 138,000-volt feeders on the Consolidated Edison system has always required the laying of new conduit lines since existing conduit systems with cables installed therein limit the carrying capacity of the 138,000 volt feeder, and in practically all cases the manholes would have to be enlarged so as to provide space for racking of the cables and installation of reservoirs. Estimates for the installation of a pipe system as compared to a conduit system for oil-filled cable have shown a saving in favor of the pipe system, and actual costs of the present installation are bearing out this fact.

In reference to Halperin's question concerning the effectiveness of the polyethylene tape seal across the joint, it is well to point out that laboratory tests were made on a joint sealed in this manner. A test joint was made and taped with polyethylene tapes. This joint was immersed in water and subjected to a gas pressure of 24 pounds from each end of the test sample for 67 hours. No leaks were found during this period. The pressure was then raised to 50 pounds and held for 100 hours. After 70 hours some signs of leaking were noted. Additional signs of leakage were noted at the end of 100 hours. The points of leakage were determined and the design improved to prevent leakage so that with the joint as installed in the line it appears that a satisfactory seal has been obtained.

Pettee questions why precautions were taken to clean and protect the inside of the pipe in the same manner as has been done for other pipe-type installations if the polyethylene jacket is considered to be a satisfactory seal. In regard to this question, we felt that it was desirable to treat the pipe in the same manner for two reasons. First, it was the first installation of this type which had ever been made, and second, it appeared to be desirable to maintain the oil in satisfactory condition so that if it ever entered the cable it would not affect the insulation, thereby adding an additional safety factor to the line.

Wiseman questions the degree of vacuum which can be obtained when an entire line is evacuated at one time. The line between Jamaica and Valley Stream was evacuated at one time by using vacuum pumps at both the Jamaica and Valley Stream ends. The line was evacuated to less than one millimeter which is comparable to values which have been obtained on individual sections.

Everest states that installation costs would be desirable. A breakdown of the installation costs was not available at the time of the preparation of the paper, and in general, this type of information is not included in AIEE presentations. Actual costs for installations in any particular locality cannot be taken as an example of costs for all areas since there is a wide variation in labor costs, installation conditions and underground structures. These data, however, will be available for presentation to other groups interested in the installation costs.

Main commented on the necessity for providing cathodic protection in addition to the external coating of the pipe. This protection is being provided as an additional safety factor since we do not desire corrosion to occur on any part of the pipe. Due to the territory through which the pipe passes, it is quite possible that external damage to the pipe coating may be caused by employees of other concerns, and this condition might not be brought to our attention until damage had occurred to the pipe. With the application of cathodic protection, the pipe would be protected from this type of damage.

Since the writing of this paper impedance and capacity tests have been made on the Jamaica–Valley Stream feeder. From these tests we are able to report the following unit values:

	Ohms Per Mile
Positive sequence impedance from data obtained during the heat run	$R_1 = 0.21$ $X_1 = 0.33$
Zero sequence impedance from zero sequence test with 212 amperes per phase made after conclusion of heat run	$R_0 = 1.31$ $X_0 = 0.45$
Zero sequence impedance calculated from line to ground and line to line tests made after conclusion of heat run	$R_0 = 1.28$ $X_0 = 0.54$

It is believed that the zero sequence reactance calculated from the line-to-ground and line-to-line tests is probably more nearly correct than the value obtained from the zero sequence test since the latter is a difference of two relatively large numbers. The difference in the resistance values given may be accounted for by the fact that the conductor temperature was somewhat higher in the zero sequence test.

Tests have been made of line capacitance in order to calculate charging current. The value obtained is 0.386 microfarad per mile per conductor. Discussion of the comments pertaining to the design and manufacture of the cable and accessories was covered by Del Mar and Wyatt.

115-Kv High-Pressure Oil-Filled Pipe Cable Installation at New Orleans, La.

Synopsis: The first major high-voltage pipe-type installation in this country to be installed without any stop joints and the first in which the cable was shipped without the conventional temporary lead sheath was placed in service in June 1947, by New Orleans Public Service, Incorporated. This installation incorporates a number of novel design features of unusual interest. The paper describes these features and reports the results of tests and studies carried out in connection with this installation.

THIS PAPER describes an installation of approximately 11 miles of 115-kv high pressure oil-filled pipe-type cable forming a portion of transmission loop within the city limits of New Orleans, Louisiana. The remainder of the loop consists of overhead steel tower line, 3.8 miles of which are of double-circuit construction and 4.9 miles, single circuit. Figure 1 shows the location of the underground line (dashed) with respect to surrounding geography and other main elements of the transmission and power supply system.

The underground installation is in two sections, one approximately $6^1/_4$ miles in length connecting Market Street steam electric generating station with Midtown stepdown transformer substation, which was a companion construction project. The other section, approximately $4^3/_4$ miles in length, extends from this substation to the double circuit section of the overhead line and continues as one circuit of the latter to the newly constructed Industrial Canal steam electric generating station. The other circuit of the double circuit overhead line returning to the juncture, continues over another route to Market Street steam electric station. An overhead 115-kv line to Gulfport, Mississippi, which forms an interconnection with electric service companies to the east, also terminates at the Industrial canal station. All lines entering the Market street station, other than the loop terminals mentioned, are of lower voltage and in underground cable, although there is an overhead 115-kv line extending north along the west bank of the Mississippi River which forms an interconnection with companies to the north. This connects to the Market Street station through 13.2-kv submarine cables, the transformation being located across the river.

For the entire installation the terrain is very flat. The soil is mostly loam and clay and in general relatively wet, the general elevation of New Orleans being such that removal of all drainage is done by pumping.

System Design

Selection of Cable Type

In determining the most desirable type of cable for this installation, consideration was given to operating records of cables of various types in this country of the voltage class involved, and to local experience in New Orleans with high-pressure gas pipe lines. Up to the time of study there had been a complete absence of inherent cable failures in service in existing low-pressure oil-filled and high-pressure pipe-type cable installations. There had been a few splice failures, and numerous oil leaks in oil-filled cable installations. The local experience with high-pressure gas pipe lines had been practically perfect insofar as durability and resistance to mechanical damage and to development of leaks were concerned, notwithstanding an inherent mechanical instability of the soil, that is, its tendency to shift under change of pressure, temperature and moisture content and to produce corresponding strains in underground structures.

It was evident that a high-pressure oil-filled pipe type of installation was particularly suited to local conditions and that if carefully engineered and installed, the underground portions could be made practically free from maintenance problems and dependable for a high degree of service continuity without the usual somewhat elaborate provisions for quick access to the lines, for pressure sectionalization, and the like, in case of failure. Accordingly, inherent strength plus simplicity were adopted as the keynotes of design, placing emphasis on quality of materials and workmanship and minimizing expenditures for underground facilities for rapid location and repair of pipe or cable failure.

Pipe

In accordance with the foregoing approach, somewhat stronger pipe was used than that corresponding to current practice—$6^5/_8$ inch outside diameter, 3/8 inch-wall thickness seamless pipe made of Grade *A* open-hearth steel, in double random lengths, weighing 25.03 pounds per foot. To simplify fabrication, thereby

Paper 48-72, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 17, 1947; made available for printing December 15, 1947.

W. R. Bullard is electrical engineer with Ebasco Services, Inc., New York, N. Y., A. D. Pettee, is chief engineer of the General Cable Corporation, New York, N. Y., and G. L. Rhodes is planning engineer with the New Orleans Public Service Incorporated, New Orleans, La.

Grateful acknowledgment is made to D. M. McGregor, A. A. Edewaard and M. C. Miller of Ebasco Services, Inc.; R. W. Atkinson, M. H. McGrath, L. Meyerhoff, J. Bower and Herman Hahn of General Cable Corporation, and to M. W. Stump, M. C. Cade and G. F. Bourgeois of New Orleans Public Service, Inc., and others in these organizations for their valuable assistance in this project.

2,500-foot length

facilitating delivery, simple beveled ends for butt welding were specified. Experiments had indicated that, with the proper technique, satisfactory butt welds could be made without the formation of internal icicles, and as an alternative it was known that external sleeves could be used. In actual construction the latter method of joining was adopted to minimize the need for higher than average care and skill in welding.

For protection of the pipe against corrosion, a coating composed of an asbestos felt-coal tar enamel combination was selected, largely because of favorable local experience over a number of years with this type of covering on high-pressure gas lines. However, in view of the higher temperatures involved in the operation of the cable installation, an enamel of higher melting temperature than that of the type commonly used on gas lines was specified.

To insure a smooth clean interior, the inner surface was wire-brushed with rotary brushes and blown out with compressed air (also swabbed if necessary) then coated with a rust inhibiting enamel that was known to have relatively low coefficient of friction in contact with the copper skid wires of the cable, and to have no significant deleterious effect on the insulating oil supplied by the cable manufacturer for filling the pipe. Both inside and outside coating were applied at the pipe mills and each length of pipe was capped for shipment.

Records of previous experience with pipe-type cable installations and local experience with high-pressure gas lines indicated that welded joints carefully made were superior to mechanical joints for leakless performance, practically all leaks of record in other installations investigated having been at gasketed connections and the like. Accordingly, insofar as was practicable, all-welded or brazed construction was employed. Joints at splices were specified to be welded. Joints in riser pipes and at the bases of potheads were required to be brazed. Weld-type joints were specified for control piping, and where weld-type fittings for such joints could not be obtained, supplementary brazing or soldering was employed insofar as it could be done without damaging operating parts.

Care was taken to locate the pipe so as to prevent accidental contact with other subsurface utilities, and electrical protection from corrosion was provided, using rectifiers, galvanic anodes, and connections to the railway negative system for potential control. Electrolysis surveys along the route of the line showed that, in certain areas adjacent to railway substations, electrical gradients were present in the earth of a magnitude sufficiently steep to preclude the use of galvanic anodes alone. At these substations, electrical drainage from the pipe to the railway negative bus was provided of a magnitude sufficient to hold the potential of the pipe somewhat below earth potential and at the same time co-ordinated with the potential of other electrically drained underground structures. At one location where the line passed under very low-potential street car rails, it was necessary to supply additional drainage by means of a small copper oxide rectifier. The fact that the pipe was welded throughout its 11 miles of length, with no insulated joints, created the problem of excessively negative pipe-to-soil potential in areas remote from the steep gradients near the substations. This was solved by placing resistance bonds between the coated steel pipe and the existing bare cast iron piping systems at strategic points, so as to raise the potential of the steel pipe adequately in these areas.

Sectionalization

In prior installations of pipe cable, semistop joints had been employed rather freely for purposes of pressure sectionalization under abnormal conditions, and for rapid location and repair of faults. Examination of designs available at the time revealed that the mechanical requirements of such joints might make it difficult to secure thoroughly dependable electrical characteristics, and while operating records showed no failures, it was felt that such joints represent a potential source of weakness. Also, piping and valve complications, that usually are incorporated in the design of semistop joints, seemed likely to be a source of maintenance expense. Methods of pressure sectionalization by freezing the oil in the pipe were investigated and found to be possible, although slower, of course, than by the use of semistop joints and valves.

Accordingly, in view of the likelihood of improving over-all electrical factors of safety and avoiding some maintenance expense, it was decided to avoid the use of semistop joints, and to accept the consequent necessity of using a slower procedure of restoring the line to service in the remote possibility of failure. Judging from existing experience records, and

considering the added security against failure provided by various measures of simplifying and strengthening design, the occurrence of pipe or cable failures should be very rare.

All splices therefore were of the straight-splice type with passages left fully open to flow of oil and with a minimum of special mechanical support and no anchoring of the spliced conductors, as described in another section of this paper.

Pulling Lengths

As mentioned previously, service failures in existing supertension cable lines at the time of study had been limited to failures of splices. This called attention to the inherently better control of quality of tape insulation under factory conditions of application, and indicated that the fewer the number of splices used in the line, the better would be the security against failures stemming from the personal element and other factors concerned with hand application of insulation in the field. Another incentive for holding the number of splices to a minimum, was the saving in cost. Accordingly it was decided to use pulling lengths as long as conservative design would allow. It was determined that a maximum length of straight pull of 2,500 feet would keep pulling tensions well within currently accepted allowable values of strain on the copper conductors. This value therefore was adopted as maximum, and splicing points were worked out with allowance for added tensions caused by bends in the pipe.

Attention was also given to sidewall pressures on the insulation caused by pulling around bends. Arbitrarily the allowable value of sidewall pressure was limited to the extremely conservative value of 100 pounds per foot of length. Splicing points were laid out and directions of pull were selected so as to keep bends principally at the feed end of pulling sections, thus minimizing the effect of the bends on pulling tension and sidewall pressure. The average actual pulling length as installed was about 2,000 feet and a very complete record of measured pulling tensions during installation indicated that the design was quite conservative. A maximum pulling length of 3,000 feet instead of 2,500 feet could have been used safely.

Typical pulling tension data are shown in Figure 2 for a 2,500-foot length and in Figure 3 for a 1,500-foot length that involved a number of bends. Table 1 shows the various lengths pulled, the equivalent straight length taking into account the effect of the bends, the estimated maximum tension, the actual tension, and the formula which was used to compute the estimated pulling force. A somewhat more refined formula, which was developed during the installation work, is also given.

Manholes

In the absence of semistop joints, and with all welded construction of the pipe and splice casings, there is little incentive to provide permanent manholes as a means of quick access to the line. With such construction all one sees in entering a permanent manhole is a pipe with an enlarged section containing the splice. In case of failure in the splice there would be some saving in time for restoration of service, but as explained later the splice was designed to have a breakdown strength greater than that of the cables. In the case of cable failure in a section between splices, the problem of withdrawing and replacing a 2,000-foot section of cable offers greater difficulties and involves the probability of consuming more time than the alternative of making an excavation at the fault and repairing it with a splice or with a short section of cable and two splices. Accordingly, it was decided to omit all permanent manholes, completely burying the line. This feature of construction is not novel, being very commonly and successfully used in Europe and South America, for cable of various types and voltage classes, and also used in this country in a few cases. Contrary to the natural conception of persons unfamiliar with such practice, location and repair of faults in buried-cable systems is not especially difficult, and faults are rarer than in conduit systems where cables in manholes are exposed to various types of damage. In the case of this installation, in addition to methods of location of electrical faults employed generally in buried cable systems, permanent test leads terminating in handholes in the sidewalk will be available for detecting or measuring pipe potential at a number of points along the line in connection with fault tracing current of various kinds. These test leads, however, were included in the design primarily for the purpose of checking potentials concerned with cathodic protection.

29 -30	2,106	2,465	7,250	6,600	+ 9.9
30 -31	1,667	1,921	5,660	5,600	+ 1.1
31 -32	1,985			5,450	

* This estimate based on a coefficient of friction of 0.30. Equivalent lengths calculated as follows:

$L^1 = Le^{ka} + ra$

L^1 = equivalent length at end of curve

k = coefficient of friction

r = radius of curve in feet

a = angle of curve in radians

L = tangent, or equivalent, length preceding curve

e = base of Naperian logarithm

Subsequent to the computation of the estimated maximum tensions shown, a refinement was made in the above formula to include the effect of the weight of the cable in the bend. The formula including this factor is:

$$L^1 = Le^{ka} + (r/k)\left(e^{\frac{Ka}{1}}\right)$$

Figure 3. Variation in cable pulling force with length of cable pulled

1,500-foot length

Figure 4. Portable manhole

In lieu of permanent manholes, portable steel manholes were used for splicing as shown in Figure 4. These were approximately 7 feet deep, 8 feet long, and 6 feet wide and were fabricated in two sections which, when bolted together around the pipe, formed a water-tight enclosure.

Thermal Tests

The required rating of the circuit was 80,000 kva at 100 per cent load factor. The various manufacturers were requested to submit proposals of cable in pipe from which it was soon evident that different basic assumptions resulted in a wide range of recommended conductor size. It was, therefore, considered best to make local thermal tests to determine the thermal aspects of the different types of cable proposed and the proper conductor size. By mutual agreement with the cable manufacturers, 600,000 circular mil conductor was chosen with 480 mil insulation thickness as standard for this voltage class.

Five types of cable were tested, including four using nitrogen as the pressure medium and one using oil as the pressure medium. Two of those using gas pressure had permanent lead sheaths. Sample sections of 3-phase circuit of each of the five types were placed in a six inch pipe and joined end to end, forming one 3-phase circuit. This was short-circuited at one end and balanced 3-phase current was introduced at the other end. The sample sections at the two ends of the pipe were each 35 feet long and the others 25 feet each. The oil-pressure section of pipe was separated from the other sections by a micarta oil stop barrier. The pipe was coated with alternate layers of coal tar enamel and asbestos pipe line felt, giving an over-all thickness of 0.2 to 0.25 inch.

Temperature gradients from conductor to pipe were measured at five-foot intervals longitudinally, and the temperature gradient in the earth was measured at the middle of each section, all by means of thermocouples. In all, over 100 thermocouples were used.

The results indicated little if any difference between gas and oil, at 200-pound gauge pressure, as mediums for carrying away heat, although the insulation of the gas-pressure samples seemed slightly less thermally conductive than the oil-pressure sample. For two particular cables without lead sheaths, Figure 5 shows a reasonably typical comparison between gas-pressure and oil-pressure samples, with gradient indicated from conductor to earth 16 feet away from pipe.

Since the test results for the particular cable dimensions involved showed a noticeable increase of temperature rise for lead-sheathed cable as compared with those without lead sheaths, it was indicated rather clearly that permanent lead sheaths constitute a handicap from a thermal standpoint because of additional energy losses due to circulating currents.

It was concluded from the results that the required 80,000 kva continuous rating would be met adequately by 600,000 circular mil conductors with a maximum allowable copper temperature of 70 centigrade in the case of oil as a pressure medium if permanent lead sheaths were not used, it being felt that the soil at the test location was typical of that along the route in the actual installation, and that moisture content would ordinarily be high.

Cable Design and Manufacture

Cable Construction

The single conductor high pressure oil-filled pipe-type cable employed on this installation has the following construction:

Conductor

Area.....600,000 circular mil
Type.....Compack Round
Diameter.....0.813 inch

Shielding: 3—2.5 mil by 0.75 inch metallized paper tapes. (Included in the insulation wall thickness.)

Insulation

Total thickness 480 mils—3, 5 and 6.5 mil paper tapes, of graded density.

Shielding: 2—3.5 mil by 0.75 inch metallized paper tapes. (Included in the insulation wall thickness.)

Tape Moisture Seal

2—7 mil by 0.75 inch polyethylene tapes each intercalated with a 3 mil by 0.75 inch aluminum tape.

Outer Bedding

2—3 mil by 0.75 inch aluminum tapes applied butted.

Skid Wires

2—half-round copper wires 200 by 100 mils applied in open helix with approximately three-inch lay.

Following the application of the metallized paper tape shielding over the insulation, several temporary protective paper tapes were applied over-all and the cable was then impregnated in the conventional manner employed with solid-type cable with *HC* polybutene oil having a viscosity of about 800 Saybolt universal seconds at 100° Fahrenheit, or about one-fourth of that normally used on solid-type cable. After impregnation, the tape seal, the metal protective tape, and the skid wires were applied and the cable was placed on weathertight reels for shipment.

Tape Moisture Seal

Prior to the New Orleans installation, all high-pressure oil-filled and high-pressure gas-filled cable in commercial service in this country had been supplied with a temporary lead sheath which served to give protection against moisture entrance during shipment and which was stripped from the cable on installation. The ever-present hazard of flash floods in New Orleans and the obvious desirability of keeping to a minimum the field operations necessary during the cable pulling gave added impetus to a development already under way on a construction in which the temporary lead sheath is omitted and protection against moisture pickup during shipment is obtained by other means. Consideration was first given to the substitution of an extruded or taped nonmetallic jacket for the conventional temporary lead sheath. This approach was discarded promptly because, in spite of the elimination of lead, there still remained an important disadvantage in that complete removal or frequent perforation of the jacket would be necessary at time of installation in order to secure substantially complete and unimpeded access of the oil pressure to all parts of the cable surface beneath the jacket. Any departure from this basic, established design principle would have introduced factors requiring long time full-scale field trials for their substantiation. It was apparent that what was needed was a type of seal which would provide effective protection during shipment and during the short time the cable was exposed in the field but which, when subjected to the high pressure employed in operation, would not noticeably impede the cyclic interchange of oil between the cable structure and the interior of pipe.

A tape seal consisting of two layers of polyethylene tape each intercalated with a suitable thickness of metal tape was found to give the desired result. The effectiveness of this seal results from a gasketing action between the intercalated metal and polyethylene tapes. Polyethylene was chosen for the purpose because it is inherently water repellent, has a very low rate of moisture absorption and diffusion, and has no harmful effects on insulating oil even though, in time, it may tend to disintegrate and dissolve in the oil at the temperatures encountered in service.

The ability of the seal to provide the degree of protection necessary has been convincingly demonstrated by numerous laboratory tests and by the experience on the commercial shipments made to New Orleans. In the laboratory, samples from lengths of cable protected by the tape seal were bent on a 48-inch diameter drum, secured in this bent position, and then exposed to an atmosphere of a 100 per cent relative humidity. During the course of the tests, samples were removed periodically for radial power factor measurements. Any moisture penetration of the tape seal either by way of the gasketed zigzag path between tape surfaces or directly through the polyethylene tapes themselves would produce a progressive increase of the power factor of the outer insulating tapes of successive samples. Results of a typical test on the seal described before are shown in Figure 6. It will be noted that the penetration of water vapor after an exposure period of as long as five months at 100 per cent relative humidity and room temperature was not sufficient to produce any significant change in the 80 degree centigrade power factor of the insulating tapes. Similar results were also obtained on samples in which the temperature was permitted to vary cyclically in a 100 per cent relative humidity atmosphere by as much as 25 degree centigrade above and below room temperature. In this connection it is pertinent to note that Piper[1] has recently reported that several months exposure to Detroit's humid summer atmosphere (out of direct contact with rain) of cable samples protected by metallized paper tape resulted in no apparent increase in the moisture content of the insulation. Piper considers that metallized paper tape alone may be sufficient to bar the diffusion of water vapor into the insulation. These results have been confirmed in a preliminary manner on cable samples protected by two metallized paper tapes and two metal tapes without the polyethylene tape. Several such samples have been exposed to 100 per cent relative humidity and room temperature for times as long as four months without change in radial power factor. This evidence tends to indicate that the seal construction as used on the New Orleans cable is conservative, and for future installations consideration should be given to the omission of at least one of the polyethylene-metal tape seal layers.

The tape seal does not alter the operating characteristics of the cable in service. This point has been verified beyond question of doubt by numerous radial-flow resistance tests carried out at high-pressure on cable lengths with and without the tape seal. These tests have shown that upon the first application of pressure the resistance to inward radial flow through the insulation is the same with or without the tape seal. After several load cycles this holds true for either direction of flow.

The development work on the tape seal, as well as the investigation by Piper, also leads to the conclusion that even when a temporary lead sheath is employed, the use of fibrous material, such as cotton or plain paper tapes, outside of the metal-

** In terms of the stress in the 480 mils of factory applied cable insulation.

lized paper tape shielding over the insulation is undesirable since such materials become saturated very quickly under humid conditions and subsequent removal of such moisture is difficult.

Weather-Tight Reel

With a tape-seal type of construction, or in fact with any type of covering which is not removed at time of installation, some precautionary measures are advisable, if not essential, to prevent water or moisture collecting on the surface of the cable because even minute amounts of surface moisture can materially increase the time and expense of conditioning, once the cable is in place in the pipe. In the case of the New Orleans cable, protection from mechanical injury and surface moisture was obtained by means of a weather-tight reel. The reel was of steel construction with all seams carefully welded. The outer layer of cable was covered by a "blanket" of metallized cloth tightly sealed to the inside of the reel flange. The material used was one developed during the war for the Armed Forces and was used extensively by them for protecting delicate machinery from moisture during shipment and storage in humid climates. A layer of specially dried wood lags was placed over this blanket, followed by a sheet of galvanized iron and a final outer layer of lags. The ends of the lags and the joint at steel rim of the reel flange were further sealed with waterproofing paper and compound. Each reel was also equipped with a pocket containing silica gel and prior to shipment was flushed with dry nitrogen gas.

Impulse Design Tests

In order to obtain as great an impulse strength as is practical, two constructions were made up experimentally prior to start of manufacture. In the first of these the thinnest tape employed was 5 mils whereas in the second the thinnest tape was 3 mils. Since a lightning-surge generator was not readily available, a novel type of switching surge generator was employed for testing. Essentially the apparatus consisted of 16–70 microfarad 3,800-volt capacitors operated in conjunction with a 2,200 to 750,000-volt 60-cycle bank of transformers. The capacitors were charged to a predetermined potential and discharged through the primary of the transformers. Discharging the charged capacitors through the primary of the transformers produces a surge which is stepped up to a value essentially determined by the ratio of transformation, the capacitance of the charged capacitors, and the capacitance of the cable sample. The surge was a lightly-damped oscillatory wave of 150 to 350 cycles frequency superimposed on a much lower frequency of 5 to 20 cycles. These frequencies were determined by the capacitance inductance constants of the circuit. With the sample length employed, approximately 33 feet, the time to reach the first surge peak was between 1,400 and 1,500 microseconds. The voltage was determined from an oscillogram obtained with a cathode-ray oscilloscope. The amplitude of the oscillogram was calibrated in terms of voltage by means of a standard 75-centimeter sphere gap.

The normal test schedule consisted of applying 25 shots at 550 kv and 2 shots at each 50 kv increment until failure occurred.

The following tabulation gives a summary of typical results obtained on the two cable constructions:

Sample Number	Surge Breakdown Kv (Crest) Minimum Tape Thickness 3 Mil	5 Mil
1	890	915
2	960	835
3	922	858
Average	924	869
Average stress (volts per mil)	1,925	1,810
Average maximum stress (volts per mil)	2,870	2,700

These values were all very high in relation to the recommended withstand stress of 1,200 volts per mil and the 3-mil construction had a small advantage. Because of these factors and because of the requirement that the line have the greatest inherent strength, the 3-mil construction was adopted for the cable as actually built.

Accessory Design

Normal Joint

In view of the decision to eliminate permanent manholes, it became desirable to insure that the joint design used would be as strong electrically as the cable itself on both normal frequency and impulse. For this reason design tests were conducted to determine the necessary creepage path length, hand applied tape thickness, and so forth.

The joint design adopted is shown in Figure 7*A*. A flush-type copper connector having the same diameter as the conductor was used to avoid the high stress region which occurs near the ends of nonflush connectors and requires special treatment. The connector was a soldered-type supplemented by pressed indents (Figure 7*B*). Long pencils were made on the factory insulation by tearing each tape individually at points approximately 0.16 inch apart. Paper tapes of the same thickness and density as those removed, were applied butt edge to match the pencil on the factory applied insulation. The hand-applied taping was then built up until the thickness was 1.0 inch, or 108 per cent greater than that of the factory-applied insulation. The hand-applied build-up was tapered at the ends

Figure 7A. Section of joint

Figure 7B. Joint connector

of the joints by tearing the successive tapes at points approximately 0.10 inch apart. The joint was completely shielded with tinsel copper braid. Polyethylene tape was temporarily applied over the completely insulated and shielded joint to protect it during construction. After all three joints were completed, the polyethylene tape was removed, splints consisting of split laminated phenolic tubing were bound in place over the individual phases, and the three splices were brought together so as to permit the use of an 8¾ inch outside diameter pipe casing. The use of splints permitted shifting the position of the completed individual joints without risk of disturbing the hand-applied insulation and in service will eliminate any possibility of buckling at the splice location as the result of compressive forces that may be set up while the cable is under load. The pipe casing was split longitudinally into two parts so as to keep the length of the temporary manhole to a minimum. The circumferential and longitudinal seams in the casing were then welded, using an electric arc.

Table II shows the essential design dimensions and impulse test results on several of the experimental joints tested. All joints were tested at 200 pounds per square inch gauge. Joint number 3 had no preliminary 60-cycle test but both of the other joints were tested for six hours at 163 kv (340 volts per mil) and six hours at 193 kv (402 volt per mil) before being tested on surge. The schedule followed on the surge tests consisted of 25 shots at 660 kv followed by one or more shots at each 50-kv step to failure. It will be noted that joints 58 and 39/48, both of which have dimensions similar to those employed in the actual installation, have impulse strengths in excess of that of the cable.

Table III shows design data and 60-cycle test results on additional experimental joints. These joints also were tested at 200 pounds per square inch gauge oil pressure. All joints also were submitted to a preliminary test of 25 shots at 660-kv impulse prior to application of normal frequency.

The Association of Edison Illuminating Companies' (AEIC) 60-cycle test schedule for the cable insulation thickness in question is shown by the dotted line in Figure 8. Except for a difference in the initial step (6 hours at 402 instead of 340 volts per mil), the schedule used was the same as the AEIC schedule up to the middle of the fourth step (588 volts per mil). Thereafter the voltage was raised at a substantially geometric rate corresponding to an increase of 20 per cent in 3 hours.

The use of a geometric rate of rise over the latter and significant portion of the test schedule up to the point of failure makes it possible to obtain a simple, direct and relatively accurate comparison on the basis of the final voltage itself and avoids the need for evaluation on a one-hour equivalent basis by using an arbitrary power law. Where the voltage is raised in large steps, or the test is made for a long time at relatively low stress, comparison between two tests can be made only by calculation with the use of an arbitrary power law.

Some previously published results on 60-cycle breakdown tests on high-pressure oil-filled cable are not comparable with the foregoing 60-cycle test results. For example, a one-hour equivalent value of 1,200 volts per mil obtained by evaluation of a test made for many hours at a stress of 400 to 600 volts per mil gives no indication whatsoever as to the actual one-hour strength of the cable. As a case in point, Atkinson[3] has reported tests on identical samples of ordinary "solid" cable and has shown that by merely extending the time of test into the range where the exponential law does not apply, it is possible to obtain equivalent values of as much as 1,200 volts per mil for a solid cable on which breakdown would actually occur in one hour at about half this stress.

Terminals

The terminal has an internal laminated bakelite pressure tube designed to withstand 200 pounds per square inch continuously. The pressure tube is sealed to the metal shells at each end with long tapered baked cemented joints, backed up by rugged stuffing glands. All terminal pressure tubes were tested to 400 pounds per square inch for four hours before shipment. The space between pressure tube and factory applied insulation is filled by a saturated paper tube.

Figure 8. Voltage test schedule for 60-cycle tests

Figure 9. Arrangement for stop tube oil supply in case of loss of pressure and oil from adjacent pipe line

Porcelain insulators are standard 138-kv bushings with withstand impulse of 650 kv and 60-cycle ratings of 335-kv dry and 275-kv wet. Co-ordinating gaps are set for 450-kv full-wave flashover.

The space between the porcelain insulator and the pressure tube is filled with cable oil and maintained at low pressure by gas in the dome. The porcelain insulator is protected against high-pressure leaks by a check valve. Expansion between conductor and the top of the pressure tube is accommodated by a slip joint, while the relative expansion between pressure tube assembly and the protective hood is accommodated by flexible straps.

In an existing pipe-type cable installation, a pothead failure, understood to have been caused by loss of pressure followed by draining of the oil from the pressure element of the pothead, had called attention to the need for some positive means of keeping the potheads filled with oil in case of loss of pressure. This was accomplished by separating the pressure tube from the line pipe by a semistop gland and supplying the pressure tube with oil from a small tank located above the top of the terminal and normally kept under oil pressure by a connection to the line pipe. The piping was arranged to trap oil in the tank in case of loss of pressure in the main pipe and to feed this trapped oil into the potheads at the base above the semistop gland which served to restrict oil flow back into the pipe, thus maintaining the pothead pressure tube full of oil for a considerable time. This arrangement is shown diagrammatically in Figure 9.

Oil-Pressure Control System

In line with the field design goal of inherent strength and dependability, vacuum is used above the oil in the storage tank in order to insure that the oil will be maintained in a well degassed condition, thus minimizing the possibility of gas bubbles in the insulation under low pressure or loss of pressure conditions.

Two oil-pressure control units are installed at Midtown substation to maintain a pressure of approximately 200 pounds per square inch gauge on the oil in the line pipe. Normally each unit supplies one of the two circuits. However, the units are so designed that either unit is capable of supplying both lines. Furthermore, paralleling valves are provided so that any main component of either unit may be used with the other. Each unit consists essentially of a pressure pump with associated check relief and solenoid operated valves, a 1,300-gallon reservoir tank mounted on the substation structure, and a vacuum pump for maintaining the oil in the reservoir under vacuum. A recording and indicating pressure gauge provides a permanent record of system pressures. Alarm relays are provided to give audible and visual signals in the event of high or low oil level or low vacuum in the main reservoir tank, as well as low oil pressure in the line pipe. A timer, which is actuated by the pressure-pump control, operates an alarm when the duration of any individual pump operation exceeds a time interval found by experience to represent normal conditions. A control switch in conjunction with a solenoid operated valve automatically controls the oil pressure variations within predetermined limits. All valves, stems, packing glands, and so forth, on the low-pressure side of the system are maintained under a small positive pressure provided by a gravity head, so as to eliminate any possibility of air or moisture entrance. To protect riser pipe and pothead stop tubes, relief diaphragms are provided, discharging into small evacuated reservoirs.

Field Construction

Subsurface Conditions

The route of the cable installation was through a congested urban area, in city streets with various types of pavement, such as gravel, brick top, 8 inch concrete and, in one location, heavy granite blocks with concrete topping. In some instances the route was under paved sidewalks or in ground with sod covering. The city, being below river level, has a very large surface drainage system of canals and pumping stations. It was necessary to cross the canals, in several instances, either by going above grade, as shown in Figure 10, or in event the canal was covered over, going either through or under it. It was necessary, in passing through canals, to weld an outer casing pipe to the carrier pipe, extending several feet beyond the canal well on each side. The space between the carrier and casing was filled with oil for thermal conductivity and vented to atmosphere for safety.

Figure 10. Overhead crossing at canal

Figure 11 (right). Cable feeding rig

The entire route was thoroughly explored with probe rods and where necessary an excavation was made to determine obstructions, providing information from which the final grade and radius of bends of the pipe were determined.

Pipe Laying, Welding, and Conditioning

The pipe was installed at depths varying from two feet in crossing of some drainage canals, to 14 feet in crossing under others; average depth being approximately four feet. The pipe was prebent locally, using cold bending for all bends of radii from 33 to 200 feet. No bends of shorter radius than 33 feet were used. All bends of radius greater than 200 feet are within the natural flexibility of the pipe obtainable during installation.

Pipe was welded above grade, generally to 300-foot lengths, thereby reducing the welding in the trench. All welds were tested to 500 pounds pressure, using a special testing device, designed and constructed locally, to build up pressure over approximately two-foot lengths of pipe each side of weld. A special water trough, fitting around the pipe and submerging the weld, was used for testing leaks, pressure being maintained over approximately 1/4 hour periods. Pipe sections were completed and at temporary pulling manholes, sealed off and filled with dry nitrogen until time for cable pulling. The pipe was exposed to the atmosphere, in some instances, several months prior to installation in the ground. No significant rusting was evidenced. At welding points, the protective interior coating was charred and consumed, leaving a bright surface on the interior. The dry nitrogen atmosphere preserved this surface until time for cable pulling. Sudden storms resulted in flooding two of the pipe sections during installation. These sections were first swabbed, then dry air was blown through the pipe until the dew point was down to below −20 Fahrenheit. Dry air was obtained by compressing air to 500 pounds, passing it through a heat exchanger, lowering the temperature to 32 degrees, then reexpanding. Pipe coating was tested prior to installation, using a small-capacity high-voltage test set connected to a spiral doughnut of wire fitting around and rolled along the pipe. Any pin holes or defects found were patched. The test voltage was approximately 26 kv. Damage to the coating from poor backfill was located by using battery supply between pipe and ground and exploratory metallic probes in the soil above and along the pipe, these being connected to a vacuum tube voltmeter. Where necessary, reexcavation and patching of coating was done.

Figure 12. Temporary baffle used in splicing

Pulling

Due to the occurrence of sudden severe storms, it was considered advisable to arrange for cable installation in such a way that no damage could result from this cause. The equipment, therefore, was designed and fabricated to permit feeding of the cable from the reels in a protective housing above grade, through a goose-neck pipe connection into the pipe in the ground. This is shown in Figure 11. Approximately five gallons of cable oil were poured into the pipe before the cable was pulled. The pulling rig had a gasoline engine powered fluid drive, with a steel boom extending horizontally over the manhole, connecting to a watertight enclosed sheave in the manhole. A sheave at the manhole end of the boom was linked with a dynamometer arranged to give continuous indication of pulling tension. The sheave diameter was designed so that, with a Veeder revolution counter the length already pulled was continuously indicated as pulling progressed. Dry air was supplied to the pipe during the pulling operation. Temporary phone communication was provided for the pulling and feeding manholes, and the pulling rate was held normally to about 25 feet per minute. It was varied from approximately 15 to 30 feet per minute during one pull to determine the effect on the pulling tension, and no considerable variation was noted. Several pulls were made during storm conditions without any indication of high humidity in the pipe. Prior to pulling cable, a cleaning plug was pulled or blown through the pipe. On the first few sections the plug

Figure 13. Pothead in process

Figure 14. Completed pothead

was followed by a vacuum cleaner. However, the residue picked up by the latter was insufficient to justify its further use. The plug was blown through the pipe with approximately fifteen pounds air pressure, with a piano wire attached. This piano wire had permanent markers soldered to it and was used as a measuring chain for a final check of the surveyed length before fixing the cutting lengths of cable. The wire was used also to draw in a 1/4-inch steel rope which served as a leader for the 3/4-inch steel pulling rope. The foreign material removed from the pipe was primarily interior coating ash left from the pipe welding process.

After the pulling operation was completed, the pipe sections were temporarily sealed with night caps until splicing could be completed.

Splicing and Terminating

The portable steel manholes, at times, were subjected to exterior flooding from storms during splicing. Humidity was controlled by a continuous supply of dry air from the air compressors which had been used in drying out the pipe. A temporary baffle plate, Figure 12, was used for sealing the pipe sections to retain an atmosphere of dry nitrogen in the pipe during splicing. The splicing was done on a three-shift 24-hour basis requiring approximately three days for a 3-conductor joint. An additional 12 hours was required, per joint, for welding the split joint casing. Tests were made of temperatures involved during welding of the split casing, and the rate was controlled so that no excessive temperature of the cable resulted.

A trifurcating head, consisting of a plate, welded to a short piece of 8 5/8 inch steel pipe, and with three copper tubes brazed to and projecting from the plate, was used for leading the conductors from the line pipe to their respective potheads. The copper tubing was protected with the same type of coating as the line pipe. Figures 13 and 14 show one of the potheads in process of assembly in a protective house, and the completed job.

Oil-Filling

After the splice and pothead installations were completed, the nitrogen was removed from the system by application of vacuum until a pressure of 2 millimeters absolute was reached. Pressures were checked at the two ends and middle of the line sections and vacuum was held without pumping for a number of hours without significant rise in pressure. Preheated oil was drawn from the tank cars, filtered and degassed by spraying into the reservoir tank under vacuum. The oil was then introduced into the pipe, requiring a period of several days for each of the two sections. The initial oil drawn from the remote end of the pipe came out clear, with only a slight amount of interior coating dust in evidence. Dielectric strength and power factor tests on the oil before and after introduction into the system were substantially the same.

Discussion

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Twenty years ago, the AIEE had presented to it a symposium of papers covering the initial commercial installations of oil-filled underground power cable. These installations symbolized cable's coming of age and they were based on developments originated by the Societa Italiana Pirelli. This and another pipe-type cable paper[1], together with work done by some other manufacturers on extra-high voltage cable systems in this country, reflect great credit on the American cable manufacturing industry. The encouragement and ideas of cable users have been of some help in such developments.

For operation at 69 kv, there is a choice of many types of cable systems, including solid-type or oil-filled cable either in ducts or buried, medium-gas-pressure or self-contained high-pressure cable, and an assortment of pipe-types. Altogether, there may be 15 types at 69 kv, about 12 types at 138 kv, and an unknown, but smaller number, of types at 230 kv. My point now is that one should not become enamored of any one type, but should approach each situation on a straight engineering basis. As experience develops, however, perhaps a few of the many types will drop out of the picture.

Of course, the simplest installation is of solid-type cable with sealed joints filled with compound and having no oil reservoirs. Such an installation of 69-kv cable was made in ducts in Chicago over five years ago and a similar, but buried, installation is to be made in Winnipeg this year.

A line of low-pressure oil-filled cable should require very little maintenance according to operating experience of recent years. Also, with such cables there is no problem of iron pipe losses which is a factor militating against the use of pipe-type cable systems for large currents. It would be interesting to learn the manufacturer's ideas as to the approximate limiting current that is feasible with a pipe-type system.

In the pipe-type cable installations, there is the possibility of between-phase failures. This means a higher interrupting duty for the existing or required new circuit breakers, or both, than for installations of single-conductor solid-type or oil-filled cable. This higher duty has militated against the use of pipe-type cable in at least one instance.

In some cases, the fact that lead-sheathed cable of any type may be installed in existing or contemplated conduit systems (that may contain other cables) makes the use of pipe-type cable systems economically unattractive.

Extensive field and laboratory tests, running up to 70,000 hours and up to 140 degrees centigrade, on cable samples, supplemented by various test data obtained on paper tapes in oil, have indicated that oil-filled cable may safely operate at higher than the standard values used in this country for oil-filled pipe-type cables. This advantage amounts to about 10 degrees centigrade for normal operation and about 20 degrees centigrade for emergency operation. Perhaps, with more test data and some operating experience, higher operating temperatures than the standard values may also be established for some of the pipe-type cable systems. It would be of interest, for example, to learn what would happen to a 69-kv polyethylene taped cable if its conductor were to operate for a week or two up to 115 degrees during an emergency.

Also, it would be helpful to learn the manufacturer's present ideas of the limiting temperature for say, 4,000 hours per year for 40 years, to which polyethylene may be subjected when immersed in oil, as described in the paper. At such temperatures, what is the expected condition of the polyethylene at the end of the assumed 40-year period?

This paper and other information have disclosed some marvelous 60-cycle breakdown test data as obtained in tests taking hours. Such data would indicate that substantial reductions in required insulation thicknesses are in order, especially for some of the pipe-type systems. However, as has been known for some time, the criterion to use in most cases is the unit impulse strength of the insulation, and this criterion has not disclosed any particular advantage for the pipe-type systems.

In general, it seems that the pipe-type cable systems will be the most suitable and economical for some conditions for operation at extra high voltages, but the nature and extent of these conditions are still being defined.

C. T. Hatcher (Consolidated Edison Company of New York, Inc., New York, N. Y.): The paper by Bullard, Pettee and Rhodes describes an interesting step in the development of pipe-type cables, namely the shipment of insulated cable without a protective lead sheath and the consequent elimination of the lead stripping operations in the field.

Protection is obtained by the use of polyethylene tapes intercalated with a metal tape. The authors state that the polyethylene tapes may disintegrate and dissolve in oil at the temperatures encountered in service. I would like to know what the temperatures are at which this condition will occur?

It is also stated that by blowing a "mouse" through the pipe for wiring the pipe it was found that some foreign material was removed. I would like to mention that we also found during the installations of our current pipe lines that the "mouse" was an effective means for removing any coating ash or welding residue from the pipe.

The authors write that a check of the actual length between manholes was made after the pipe was installed before the cable cutting length was specified. In our current installations it was necessary to specify the cutting lengths before the pipe was installed. The lengths were carefully checked from scale drawings and field surveys and the cutting lengths determined. This worked out satisfactorily, thereby determining that it is not necessary to wait for completion of the pipe.

G. B. Shanklin (General Electric Company, Schenectady, N. Y.): The paper by Bullard, Pettee and Rhodes is of great interest and value, since it describes the first installation of high-voltage cable where a lead sheath protective covering has been dispensed with entirely and an organic jacket has been substituted.

The best construction of polyethylene protective jacket requires careful thought and study. The one used in New Orleans included only two polyethylene tapes, intercalated with and backed up by metal tapes. There has been a good deal of experience with "two-tape" jackets and insulations and it is well known that a laminated multitape construction is required to eliminate, or rather to cover up all flaws and defects. It is accordingly plain that the metal tapes are relied upon more than the polyethylene tapes in this construction. Metal tapes will seal against entrance of water vapor into the insulation but are not a very reliable seal against entrance of free water and oxygen. The two polyethylene tapes must have been incorporated for this purpose, and to assure against any flaws or defects in these two tapes, special gas-tight shipping reels were used, including dryers and a neutral gas atmosphere. Provided these reels are not damaged during shipment, this furnishes adequate protection during long-time shipment exposure and also good protection during the shorter period of installation exposure.

The special gas-tight shipping reels, however, represent a very appreciable increase in cost as compared with the more ordinary shipping reels, and this raises a question whether it would not be sounder design practice to invest more of the total cost in a more rugged polyethylene jacket and a lesser cost in shipping reels without an attempt to make them gas-tight but weatherproofed sufficiently to prevent wet conditions in the rain. We have found that a multitape construction of this kind with intercalated polyethylene and metal tapes is more reliable and less costly than a relatively heavy extruded polyethylene jacket and requires about the same degree of protection during shipment.

It is interesting to note that all precautions were taken to eliminate impurities from the system in New Orleans. We fully agree that this is sound practice because the jacket cannot be depended upon during long years of service in sealing the insulation against any impurities that might be left in the pipe.

Such impurities have great affinity for impregnated paper insulation, and no type of organic jacket is permanently impervious to such impurities.

There is no sectionalization of any kind in this installation and this raises a question of whether the relatively small additional cost of semistop joints for sectionalization is not justified. Sectionalization of this kind offers a number of advantages. It allows prompt complete treatment and final filling of the system as the work progresses and thereby reduces the chances of absorbed impurities in the insulation, particularly at the joints. This also offers a chance to anchor the cable in the pipe to prevent a cumulative movement. Doubtless the extremely flat profile in New Orleans did not require this, but where rugged profile with long slopes is encountered anchoring of the cable is important.

One of the most important functions of this kind of sectionalization is to prevent contamination of long sections of the line in case of service failures and to facilitate future maintenance and repair work. Location of leaks is also greatly facilitated in this way. In deciding upon a system design these advantages must be weighed against the additional cost that they represent. All previous high-voltage cable installations in this country have had sectionalization of one kind or another because of the heavy investment involved, and its elimination represents a new departure and a great deal of faith in the integrity of the system.

Guy Everest (The Okonite Company, Passaic, N. J.): Was any consideration given to bell end pipe and use of chill rings or bell and spigot pipe, because both of these types would have been less expensive than the external sleeves for welding? External sleeves double the cost of welding compared to these types.

Corrosion Protection on Pipe

Was there any record of the pinholes or "holidays" in this coating? It has been our experience that the extruded type of corrosion protection is better to handle and has less "holidays" per length of pipe.

It appears the wrapped type of coating together with electrical protection from corrosion was used.

Was this decision to use both forms of protection based on local pipe experience or was the cost the ruling factor?

Sectionalization

Semistop joints have proved satisfactory in the field and long-time high-voltage tests on them have shown them to be equal in strength to the cable. Maintenance on the semistop joints is nil provided they are properly installed, and they facilitate installation and allow oil submersion of the cables shortly after they have been pulled in.

It appears that this installation has been designed so that the weakest point is the end termination.

It has been found that there is a difference of opinion among engineers over the country as to whether it is better to have a pothead failure, a joint failure, or a cable failure. Some prefer a pothead to fail because of the ease of replacement, provided suitable means are taken to prevent pieces of porcelain from damaging equipment close by. Others prefer cable failure because of the position, namely, underground, where least damage can occur to other equipment or the public. Others prefer a joint failure because of ease of repair and location, with possibility of damage to equipment or the public being remote. Consequently, this calls for different designs.

Thermal Tests

It is unfortunate a higher conductor temperature, say 70 degrees centigrade, was not obtained in these tests. It is known viscosity of the oil has a considerable effect on the thermal resistance of the oil zone. If the 70 degrees centigrade temperature had been obtained, a greater difference between oil and gas cable in favor of oil would have occurred.

Moisture Seal

We agree pipe-type cables can be shipped in sealed reels eliminating the use of lead sheaths by a suitable tape seal over the insulated cable.

Impulse Test

Can the method of impulse testing be compared to AIEE standards where a $1^1/_2 \times 40$ micro second wave is used? It is probably not comparable and therefore misleading. Can some clarification or test data be given to show the comparison?

Joints

So far as we are concerned it is imperative that joints can be tested similarly to the cable under Association of Edison Illuminating Companies' time tests and the two correlated so that joint is equal to or better than the cable. Our field experience in installations of 15 years' service shows this practice is satisfactory.

It would be interesting to know the total cost per mile of this installation and perhaps a breakdown of the manhours used for pipe installation, that is, welding, excavation, testing and cable installation on such as cable pulling, jointing, terminating, pipe evacuation and oil filling.

W. R. Bullard, A. D. Pettee, G. L. Rhodes: Shanklin has made some very appropriate comments on the tape seal. The effective-

ness of the seal is undoubtedly due to the multiplicity of tapes. Two metallized paper tapes, two pairs of intercalated metal and polyethylene tapes, and two metal tapes make a formidable barrier against air, moisture and water, without preventing free transfer of the fluid insulating medium. We have even immersed the bent cable in water for 120 hours at 50 degrees centigrade plus 16 hours at room temperature without detecting any significant change in the radial power factor.

Shanklin has misinterpreted our description of the weathertight reel. Reasonable effort was made to make it weathertight without excessive expense, but it is definitely not designed to hold pressure. A reel designed to stand as little as five pounds per square inch would run into too much unnecessary cost.

With regard to the absence of sectionalization, the advantages of semistop joints mentioned by Shanklin were recognized, but after careful study, they were considered to be of minor importance and outweighed by the disadvantages. As pointed out by Everest, such joints have not given trouble in service to date and the results of high-voltage tests have been valuable. However, it is obvious that in operation, mechanical stresses, due either to differential pressures in the pipe or due to expansion or contraction of the cables, are imparted to the cable insulation at the pressure seal.

Some recent tests and studies have revealed that considerable forces of tension or compression can be built up at points of cable anchorage due to load cycles and the like. These problems are being solved on other lines but they require the incorporation of special features in addition to the semistop gland which is designed primarily to check the flow of the filling medium.

An incidental advantage that has been found to accrue from the absence of semistop joints is that pressure control under normal operation is facilitated by the free flow of oil throughout the length of pipe, because there is an absence of restrictions to flow which are present in lines of conventional design with semistop joints and their small by-passes.

With respect to filling the pipe with oil, the method of filling from the end of the line after the cable was completely installed was found to be very successful at New Orleans.

Everest has asked whether the use of bell and chill ring or bell and spigot pipe was considered for the New Orleans installation. The selection of the external sleeve with its double weld was made to facilitate pipe delivery and does not indicate that the other types of pipe connections would not have been acceptable as to physical merit.

With respect to corrosion protection, as mentioned in the paper, pinholes or "holidays" in the coating were carefully located by electrical means, and patched. The wrapped type of coating was selected because of previous favorable local experience with this type. Cathodic protection was considered to be a desirable adjunct to the protection afforded by the coating and probably would have been used if any other type of coating had been selected, because it is believed that no presently practicable type of coating is completely immune to development of defects after installation, including of course punctures from external causes.

Everest has discussed the relative electrical strengths of the cable, joints, and terminals. For this installation, neither joint nor terminal was deliberately made the weakest link. Because the joints were made electrically stronger than the cable, and the impulse basic insulation level of the terminals (650 kv) is lower than that of the cable, the electrical strength of the terminal may be considered the weakest link. Further than this, the terminals and cable have been protected by co-ordinating gaps at the terminal insulator set for 450-kv full wave flashover.

Everest has mentioned the "known" effect of viscosity of the oil on the thermal resistance of the oil zone, and has regretted that the thermal tests were not carried on with a conductor temperature of 70 degrees centigrade. We do not have any quantitative comparative data on this point and it is unfortunate that Everest did not present data to indicate its relative importance. Data on this point with an oil having a viscosity of 700 Saybolt universal seconds at 100 Fahrenheit may be found in the Sanderson, Sticher and McGrath paper.[1]

In comment on his question as to the comparison between the standard AIEE $1^1/_2$x40 wave and the long wave of the switching-surge type that was used in testing the cable and joints, we do not have complete enough data to establish definitely this relationship, but from a study of all available published and unpublished data, including our own, we are led to the conclusion that the impulse strength as developed by the type of wave we used cannot be much different from the strength that would be developed by the $1^1/_2$x40 wave. Probably the former would not be higher.

It should be kept in mind that while a steep wave front has an enormous effect in changing the voltage distribution in tests on electrical equipment with wound coils, the steepness of the wave is of no such importance in a cable.

We expect in the near future to have definite comparative data on this point.

Halperin and Hatcher have asked for data on the softening or disintegration of polyethylene in hot oil. We have no data that would foretell the condition of polyethylene after 40 years of service. A two-day free suspension of clear polyethylene slabs (dumbbell shape) .075 inch thick, in a natural petroleum oil with a viscosity of 57 Saybolt universal seconds at 210 Fahrenheit (approximately 9.25 centistokes) gave the following results:

	Tensile Strength, Lbs Per Sq In.	Elongation, Per Cent
Original	1,450	700
After 2 days at 75 degrees centigrade (some swelling)	1,140	580
After 2 days at 80 degrees centigrade	Too soft to test	
After 2 days at 85 degrees centigrade	Dissolved

SOME YEARS AGO The Detroit Edison Company was faced with the problem of procuring for its system, underground cable that was to be operated at 120 kv and was to be capable of transmitting 95,000 kva continuously.

There were only two types of cable that had been used in this country for voltages above 100 kv and for loads of this order, namely, the oil-filled cable (Pirelli-type) and the Oilostatic type of cable. The Detroit Edison Company was anxious, however, to give consideration to all high-voltage cable in commercial use here and abroad, but was unwilling to adopt a cable type that had no operating record for loads of this order, without first conducting considerable experimental work.

One such cable type of which there was no installation having the required capacity was the Hochstadter[1] pipe-type, gas-compression cable. It was decided to provide an experimental field installation of this type of cable in order to determine its behavior when designed for 95,000 kva at 120 kv and operated under various conditions that might occur in service operation. Also, the successful operation in England of the Beaver type[2] of high-pressure, gas-filled cable at 132 kv suggested the possibility of its use here, and a length of high-pressure, gas-filled cable was to be included in the experimental installation, but with the important modification that all three cables of the 3-phase line would be pulled into one steel pipe instead of employing individual lead pressure containers for each conductor as had been the custom up to that time for Beaver-type cable. This modified type of cable is referred to as the *SMD* type of cable in this paper.

One of the major reasons for the 1941 experimental field installation was to gain experience in the installation and the operation of gas-pressure, pipe-type cable; another was the procurement of experimental data concerning the electrical performance of the insulation, such as can be obtained from power factor measurements that are made under various test conditions; and still another reason was to determine the temperatures and temperature distributions obtaining in such a cable installation during various loading schedules. It is at once apparent that such an installation lends itself readily to a study of various kinds of other pipe-type cable that might be considered from time to time, as well as a study of the merits of modifications in existing types of pipe-line cable—for instance, the determination of the minimum insulation thickness that is practicable for certain conditions of service operation.

Some of the results and experiences gained with the experimental installation and with a commercial installation constructed subsequently were reported in two previous papers.[3,4] Little information was given in these papers concerning thermal characteristics of the cable installation, mainly because there was only a little information available at that time. The present paper, therefore, deals exclusively with the thermal characteristics, and with other phases only insofar as they have a direct bearing on or relation to such characteristics, in the hope that these results may be of aid in the design of pipe-type cable systems.

General Layout of the Experimental Installation

A schematic diagram of the general layout installed at Warren Station is given in Figure 1. Section *A* is equipped with trifurcating heads at the pipe ends, and with $3^3/_8$-inch outside diameter copper riser pipes to the terminals. Sections *B* and *C* are connected by means of a joint in manhole *12519* and their extreme ends terminate in risers similar to those of section *A*. Between the adjacent terminals of section *A* and section *B* are located the transformers for supplying the cable loads. At the extreme terminals of section *A* and section *C* the free ends of the cable were connected by means of suitable switching equipment to an existing 120-kv overhead line, for the completion of the loop circuit. For this arrangement, the supply transformers were designed for the loading of the cables under test so that a conductor temperature of 70 degrees centigrade could be obtained. In October, 1945, when it became desirable to reach higher conductor temperatures, it was necessary to discontinue this loop arrangement by shorting the terminals at the extreme ends of the cable installation and applying single-phase 120-kv potential, because the 3-phase overhead return circuit of 250,000-cir-mil conductors caused too much loss in the transformers.

While cable sections *A* and *B* are connected in series electrically, they may be made entirely independent of each other as far as maintenance of gas pressure is concerned. Each of the two pipe systems is provided with nitrogen feeding equipment consisting of a standard cylinder of dry nitrogen and a gas-pressure regulator with pressure gauges; in addition, each is equipped with a low gas-pressure alarm set for a pressure of 200 pounds per square inch.

An important question in the operation

Paper 48-73, recommended by the AIEE insulated conductor committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 10, 1947; made available for printing December 19, 1947.

W. D. Sanderson and Joseph Sticher are both with the Detroit Edison Company, Detroit, Mich., and M. H. McGrath is with the General Cable Corporation, New York, N. Y.

The authors are indebted to many of their engineering associates who have so generously contributed to this work and wish to specifically thank M. O. Boyd, A. E. Featham, R. H. Hiester, F. M. Hull, L. I. Komives, H. D. Lewis, G. B. McCabe, R. J. McCausey, J. B. Mulavey, and W. A. Sinclair for their helpful co-operation.

of pipe-type cables is the protection of the pipe against corrosion. As a result of a comprehensive survey, the exterior of the steel pipes is protected along the length of the cable run with four different types of corrosion-preventive coverings that were selected as having sufficient merit for trial. A description of these coverings is given in Appendix I.

It was appreciated in the original planning that it would be desirable to have the sections of pipe that were to have different coatings isolated from each other, electrically, but this was found not to be practical. However, at the end of the test it is expected that the variously coated pipes will be cut apart and their respective insulation resistances measured.

Cables, Joints, Terminals and Accessories

The types of cable that are now or have been under test in this installation include the armored type of compression cable in which the insulated conductors are individually leaded, then cabled, and the whole provided with an armor; the unarmored type of compression cable in which the armoring is omitted; and various *SMD*-type cables, some preimpregnated and others mass-impregnated. A description of the various types of cable used in the successive tests is given in Appendix II. Construction of the joints, terminals, and other accessories such as compensators for the gas-compression type of cable was described in papers[4,4] previously referred to.

Provisions For Artificial Loading

The equipment for circulating current through the cable was fed from the 4,800-volt station house service feed. The rotor of a 4,800-volt 300-kva, 10 per cent, 3-phase regulator was supplied 4,800 volts, and its stator was supplied at 240 volts by a bank of three 100-kva 4,800- to 240-volt transformers. This arrangement provided 0 to 480 volts on the regulated side of the regulator. This variable voltage was connected to a bank of three 100-kva loading transformers, 500-volt to 200-volt ratio, having the 200-volt winding insulated with 139-kv class insulation and in series with the cable.

Provisions For Obtaining Thermal Characteristics

To procure the desired data of the thermal characteristics of the experimental installation, thermocouples were originally provided at 58 locations. One was placed on the shielding tape of one conductor of the cable in section *A*, in the vertical riser at the station end about one foot below the lower end of one terminal, in order to check for excessive cable temperatures in the vertical risers. In order to determine whether excessive temperatures develop in a joint, three other thermocouples were placed on the shielding tape of one conductor of the 3-conductor joint between sections *B* and *C*, one at the center, another at the end of the joint, and the third six inches from the joint wipe on the cable. The remaining 54 thermocouples were grouped in three locations along the length of the cable run in order to enable determination of the temperature distribution from the cable to the surrounding earth up to 20 feet distant from the cable in a plane perpendicular to the cable run. A relocation of thermocouples from section *B* to supplement those at the temperature station on section *A*, in January, 1943, resulted in the present layout as shown in Figure 2. Thirty thermocouples are installed at this location.

In each of the three locations along the cable run in which the temperature distribution from cable to earth is to be determined, a potentiometer type temperature recorder was installed that provides consecutive printing on a strip chart of temperatures from sixteen different thermocouples. With time intervals between consecutive printings of about one minute, the temperature of each thermocouple connected is printed approximately every fifteen minutes. The temperature range is from −20 to 80 degrees centigrade, and the potentiometer is automatically standardized. Housings were erected in the three locations to accommodate the temperature recorders. These houses were thermally well insulated, and provided with electric heaters and ventilators, so that the temperature inside could be maintained essentially constant throughout the year for the proper functioning of the recorders. In early 1943 the temperature station on section *B* was discontinued except for thermocouples on cables and pipe.

The wire used for the thermocouples was copper and constantan of 1938 calibration. The measuring junctions were of number 30 (American wire gauge) wire insulated with enamel and a single layer of silk, and in no case exceeded a length of $3^1/_2$ feet. These wires were connected to copper constantan leads of number 14 (American wire gauge) of sufficient length

Figure 2. Cross section through experimental line indicating disposition of thermocouples

to reach the temperature stations, the leads of each thermocouple being installed in conduit consisting of 1/2-inch copper tubing buried in the ground. The conduit was used in order to prevent moisture from penetrating the insulation of the thermocouple wires with consequent inaccuracies in the temperature measurements; the high thermal conductivity of the copper conduits would, however, also affect the temperature of the measuring junction, unless proper precautions were taken. The conduit therefore was laid along isothermals for at least nine feet wherever it was considered necessary. In Figure 3 are shown the types of thermocouple installations employed in the three locations where temperature distribution from cable to ground was to be determined. Part (A) of that figure shows the type of thermocouple used for measuring the temperature at the outer surface of the cable including means for bringing the lead wires out through the wall of the steel pipes; part (B) shows the type used for burying in the pipe trench in the vertical line above and below the pipe; and part (C) shows the type used for placing in undisturbed earth in the horizontal line at right angles to the pipe axis.

In order to secure data concerning ambient earth temperatures adjacent to section *A*, an installation was made in late 1941, consisting of eight thermocouples to a depth of seven feet. The type of construction is as shown in Figure 3(B).

Inasmuch as the current-carrying capacity of buried, pipe-type cable is greatly affected by the thermal resistivity of the soil, and little information was available in this respect, provisions were made for determining the thermal resistivity of the soil for different types of soil under varying seasonal conditions. For this purpose, a device is used which consists of a copper cylinder, 12 inches long, 3 inches in outside diameter, with 1/8-inch wall, provided with an internal electrical heating element capable of dissipating 200 watts uniformly over the outside surface. A copper-constantan thermocouple is imbedded in the midpoint of the cylinder wall. The general construction of this device, known as a soil resistivity cell, is shown in Figure 4, and further details for the construction and use of this cell are given in the literature.[5] This cell was buried vertically in the ground, with the heater supply and thermocouple leads brought out to a convenient location. Means were also provided for measuring the ambient earth temperatures.

Provisions For Obtaining Power Factor Data

Provisions were made for obtaining power factor voltage and power factor temperature characteristics of the cables used in the experimental field installation at various voltages in the range from 20 kv to 100 kv between conductor and ground. For this purpose, a Schering Bridge, properly modified to take care of the large charging currents encountered with these long samples of high-voltage cable, was provided. Over-voltage safety devices were employed to protect operator and equipment in case of cable failure or breakdown of the standard capacitor during measurements. The standard capacitor was of the gas-pressure type, operating at a nitrogen pressure of 250 pounds per square inch and usable for voltages up to 150 kv. Precautions were taken in the construction of the outdoor test bus connecting the cable terminals with the measuring setups, so as to minimize inaccuracies in the power factor measurements resulting from changing weather conditions and field distributions in the space of the outdoor station structures through which the test bus was installed.

Loading Schedules

With regard to the loading of the cable in the experimental installation, two distinct purposes were to be served with the original cables placed under test. First, the length of the loading periods was to be sufficient to produce essentially constant temperatures in order to enable the study of the thermal characteristics of the cable installation; second, the number of load cycles was to be as great as possible in order to obtain a maximum amount of mechanical working of the experimental installation in a given time. This second purpose was achieved by subjecting the cable to three or more load cycles a day,

each cycle consisting of a loading period of several hours followed by a cooling period of equal duration. The effect of approximately 300 load cycles of short duration on the mechanical movement of cable in the experimental installation has been discussed in other papers.[3,4] After completion of the loading schedule for satisfying the second purpose, all further loading was on the basis of loads of long duration for the purpose of obtaining the thermal characteristics of the cable installation.

Originally, provisions were made to insure that the maximum conductor temperature did not exceed 70 degrees centigrade. However, loadings were increased from time to time until a conductor temperature of approximately 100 degrees centigrade was employed in some of the tests. The length of time during which different cable samples have been subjected to various load conditions is shown in Table I. During these tests, four cable failures have occurred. One was due to charred insulation following an attempt to braze a leaking copper riser pipe with the cable in place. Two were in the 400-mil insulation of type *D* experimental cable. These were due to irregularities in taping associated with the experimental use of 1.5-mil tape in the inner portion of the insulation in combination with a relatively high maximum stress (264 volts per mil). The fourth was in the original type *A* experimental cable and occurred as the result of cumulative dielectric loss due to moisture absorbed during manufacture without humidity control. The conductor temperature in the vicinity of the failure is believed to have been well in excess of 90 degrees centigrade for an appreciable period before failure. Regarding the locating of these failures, capacity measurements from each end of the line locate a fault approximately. Burning current is then applied to reduce the resistance of the fault. Finally, Kenotron current is used to produce a discharge across the fault at about 5-second intervals, and the resulting "bump" facilitates quite exact location of the fault through the use of an electronic stethoscope. For repair of the fault, a segment of pipe 6 inches wide and 7 feet long is removed with a Skilsaw. After repair, a light foil liner (slightly larger than the slot in the pipe) is inserted over the cable as a heat radiation shield. A curved steel plate is then welded in place over the pipe opening.

Thermal Characteristics

The path of heat flow for a high-pressure, pipe-type cable divides naturally into four elements, namely, the cable insulation, compression medium, pipe coating, and the soil. It is essential that a thorough knowledge of the thermal constants of these paths be obtained if the most economical conductor size is to be selected to carry a given load. In a problem of this nature, some of the data can be obtained more readily in a laboratory setup than in an experimental field installation.

Laboratory Tests

Oil Versus Gas as Compression Medium

One of the laboratory investigations was concerned with the heat flow through the compression medium, first, when nitrogen gas is used as the compression medium, and second, when the nitrogen is replaced with oil having a viscosity of 700 Saybolt Universal seconds at 100 degrees Fahrenheit. In this investigation the cable setup was constructed from solid-type single-conductor 750,000-circular-mil paper and lead cable, with 16/32-inch insulation thickness, from which the lead sheath had been removed. Two layers of soft copper tape, 3/4-inch wide by 0.005-inch thick were applied over the insulation, butt wound with a 50-per cent overlay. Over the copper tapes, a $2^1/_2$-inch wide canvas tape, impregnated with paraffin, was applied half-lap wound; and over the canvas, number 8 (American wire gauge) bare, soft-copper wire was wound in a 2-inch open spiral.

Three pieces of the cable were assembled to form a 3-conductor cable; two conductors of this 3-conductor cable were connected at each end in such a manner that the three conductors were connected in series. The conductor forming the center of this series arrangement was 13 feet long, the other two conductors 16 feet each. The connections of the

* These values are considered to be in error due to the fact that the thermocouple imbedded in the conductor was not securely held in the well drilled for it in the conductor.

** These values were calculated from the data obtained on the conductor with the 450 mils of insulation.

*** Calculated from the shielding tape temperature by means of formula given in text.

conductors were made by pencilling the insulation, 45-degree angle, soldering the conductors together, and insulating the joints with several layers of varnished cambric tape. The test sample was then provided with six copper-constantan thermocouples, placed in a plane perpendicular to the cable axis and located at the center of the cable length. Three of the six thermocouples were installed in the three conductors, and the remaining three were tucked under the layers of soft-copper tape provided over the insulation. This simulated 3-conductor cable was then installed in a 6-inch steel pipe 15 feet long, the ends of which were provided with pressure-tight terminals. Three thermocouples were installed on the outside of the steel pipe in the same plane in which the thermocouples in the cable were located. One thermocouple was placed at the bottom of the pipe on one side, and one on top. The setup was then installed in free air.

The pipe was first filled with dry nitrogen, and tests were conducted at 200 and at 100 pounds per square inch. The nitrogen was then replaced with 700-second oil, and thermal characteristics were determined at 200 and 100 pounds per square inch. Direct current of sufficient magnitude to obtain a conductor temperature of approximately 70 degrees centigrade was provided by two welding generators. In every case, loading was continued until temperature equilibrium of the system had been obtained for four hours.

A summary of pertinent data, together with calculated thermal resistances and resistivities for these conditions is given in Table II. In addition to the data concerning the path of heat flow through the compression medium for which this phase of the study was mainly undertaken, other data that were readily obtained during the test are also included in this table. This additional information is in connection with the heat flow through the insulation of the solid-type cable used and the heat flow from the pipe surface to the surrounding air. The results concerning the heat flow through the compression medium indicate that better thermal characteristics are obtained when the nitrogen is replaced with 700-second oil. In this connection it must be kept in mind, however, that the thermal resistance of the compression medium constitutes only a small part of the thermal resistance of the complete path of heat flow of the cable installation. It is also indicated by the results that the degree of oil pressure has little effect on the thermal characteristics, whereas the degree of gas pressure has a definitely measurable effect.

Thermal Characteristics of Path Through the Pressure Medium as Affected by Position of the Cables in the Pipe

In this laboratory investigation the setup was similar to that of the previous investigation, except that the cable was constructed from *SMD*-type, single-conductor, 400,000-circular mil cable with 400-, 450-, and 500-mil insulation thickness, respectively, employed for the three conductors. The pipe was filled with dry nitrogen at 200 pounds per square inch, and a conductor temperature of approximately 80 degrees centigrade was used. Measurements were made, first with the pipe in the starting position, then with the pipe rotated 120 degrees, and finally with the pipe rotated another 120 degrees in the same direction in order to change the position of the cables in the pipe. A summary of pertinent data resulting from this investigation is given in Table III. Here again, other data are included, such as those covering the heat flow through the cable insulation and the heat flow from the pipe surface to the surrounding air.

The values measured for the conductor temperature of the 500-mil insulation sample appeared to be out of order from the beginning of the test, inasmuch as these temperature values should have been higher than those for the samples provided with the 400-mil and 450-mil insulation. When the test setup was disassembled it was found that the thermocouple imbedded in the conductor of the 500-mil insulation was loose, that is, not securely held in the well drilled for it in the conductor. Also, near the end of the test the thermocouple circuit opened inside the pipe and, consequently, further measurements could not be obtained.

The conductor temperatures measured for the 500-mil insulation sample cannot, therefore, be regarded as valid, and calculated thermal resistances for this sample based on the measured conductor temperature must also be considered to be in error. Inasmuch as the thermal resistances given for the 400-mil and 450-mil insulation samples are probably correct

and their ratio is that which one would expect from the ratio of the geometric factors of these two samples, the thermal resistance of the 500-mil insulation sample can be calculated by using the experimentally determined thermal resistances for the 450-mil insulation sample and the corresponding geometric factor with that of the 500-mil insulation sample. This was done and the values so calculated are shown in Table III. These same comments hold true in connection with the results given in Table IV.

It is interesting to note that, while the position of the cables in the pipe has no effect on the thermal resistivity of the cable insulation, which is obviously correct, and no effect on the surface resistivity from pipe to the surrounding air, the effect on the thermal resistivity for the part from the cable to the pipe is quite pronounced.

Effect of Gas Pressure and of Temperature on the Thermal Characteristics of *SMD*-Type Cable

In the experimental field installation, conductor temperatures under certain conditions were determined by means of resistance measurements of the conductors. This applied mainly to cables in section *A*, and to cables in sections *B* and *C* only when the cables in these sections, which are permanently connected to each other by means of a manhole joint, were not of a dissimilar conductor size. There were occasions, however, in which cables of dissimilar conductor size were connected in series in these sections, and this made it impractical to apply the method of conductor resistance measurements for determination of conductor temperatures. For use in such cases a formula was developed which allowed calculation of the conductor temperature from data normally obtained in connection with the field tests, if the thermal resistance values of the conductor insulation are known. This formula is as follows:

$$T_c = \frac{T_s + I^2 R_{th} R_r (1 - T_r \alpha_r)}{1 - I^2 R_{th} R_r \alpha_r},$$

where

α_r = temperature coefficient of conductor resistance at reference temperature T_r

I = conductor current, amperes

R_r = conductor resistance at reference temperature T_r, ohm per foot

R_{th} = thermal resistance from conductor to shielding tape, degrees centigrade per watt per foot

T_c = conductor temperature, degrees centigrade

T_r = reference temperature for which conductor resistance is known, degrees centigrade

T_s = shielding tape temperature, degrees centigrade

Note: Ceramic Tube Wound With Chromel Wire To Dissipate 200 Watts At 120 Volts

Figure 4. Soil resistivity cell

Figure 5. Time-temperature curves for component parts of the thermal circuit

Cables type *G*, *H*, and *I*

This formula is strictly applicable only when the dielectric loss and other losses are negligible as compared to copper loss.

One case in which test cables of dissimilar conductor size were connected in series involved 400,000-circular mil, *SMD*-type cable that was connected to 650,000-circular mil cable of the compression type. The 400,000-circular mil, *SMD* cable was provided with an insulation thickness of 400 mils for one conductor, 450 mils for another, and 500 mils for the third. It was intended to load the cables in such a manner that conductor temperatures of the order of 100 degrees centigrade would be reached in the 400,000-circular mil conductor. For this purpose it was necessary to know the thermal resistance value of the conductor insulation, and particularly whether this value changes greatly with variations in gas pressure and in temperature.

The same test setup that was described for the study of the effect of position of the cables in the pipe on the thermal characteristics was used in this investigation. The pipe was filled with dry nitrogen, and tests were conducted at 200 and 100 pounds per square inch, and atmospheric pressure, with the conductor temperature at approximately 80 degrees centigrade. In addition, one test was conducted with a gas pressure of 200 pounds per square inch and a conductor temperature of approximately 45 degrees centigrade. In every case, loading was continued until temperature equilibrium had obtained for four hours. Pertinent results in this investigation are given in Table IV. Here again, other data that were readily obtained during the test are also included in addition to the data concerning the path of heat flow through the conductor insulation for which this phase of the study was mainly undertaken. Some of these additional data are discussed under "Field Tests–Surface Resistivity from Cable to Pipe," together with data obtained in the field.

Concerning the effect of pressure on the thermal resistance of the conductor insulation it appears that any change between 200 and 100 pounds per square inch is so small that it would be masked by the experimental uncertainty of the method. At atmospheric pressure, a small increase of thermal resistance over that at 200 pounds and that at 100 pounds per square inch is indicated. It will be realized, however, that the thermal resistance at atmospheric pressure is essentially of academic interest only, inasmuch as the cable will not be operated at that pressure.

Regarding the effect of temperature on the thermal resistance of the conductor insulation, it appears that in the range of conductor temperatures from 80 to 45 degrees centigrade, the increase in thermal resistance with decrease in temperature is in the neighborhood of 10 per cent.

Field Tests

Temperature Surveys

From the tremendous amount of temperature data that have been procured from the field installation, some specific data have been selected in order to show the relative temperatures that obtain in various parts of the field installation under certain operating conditions.

In one test run the cable was subjected to 3-phase loading that was calculated to bring about conductor temperatures of

* All conductor temperatures in table were calculated by means of formula given in text, except this one which was determined from conductor resistance measurements.

approximately 100 degrees centigrade. Figure 5 was prepared to show the variation of temperature with time of loading for various locations in a plane perpendicular to the pipe axis. The load currents given in this figure refer to the currents in the Y-phase which contained cable of type *G*. The currents in the X-phase (type *H* cable) and the Z-phase (type *I* cable) were approximately 600 and 700 amperes, respectively, when the current in the Y-phase was 650 amperes. This unbalanced load could not be readily alleviated, and this unbalance must be kept in mind when considering such temperatures as those of the shielding tapes. Figure 5 affords an interesting insight into the time lag of temperature at various radial distances from the cable conductors. Figure 6 is included to show in greater detail the temperature changes that occur in the various locations during the first 15 hours following application of the load; and, Figure 7 gives a more detailed picture of the temperature decay resulting when the load is discontinued and the temperature increase that occurs when the load is reapplied. Figure 8 was constructed from data obtained from another test run that was terminated when type *A* cable failed on September 15, 1946. This figure gives an excellent indication of the length of time required for the temperatures to return to the values that obtained before the cable was loaded.

The decay of temperature from the pipe to the "sink" is another temperature distribution that is of interest, particularly in connection with mutual heating effects between two or more cable runs buried in parallel. Figure 9 shows the temperature distribution that prevailed on October 15, 1947, during the test run for which other data are contained in Figures 5 to 7, inclusive. The following tabulation shows the temperature rise above "sink" and the percentage distribution of this rise as a function of horizontal distance from the pipe.

Horizontal Distance from Pipe	Temperature Rise, Centigrade, Above Ambient	Per Cent of Total Rise
7/16 inch (outer surface of pipe covering)	36.4	100
6 inches	28.6	78.5
1 foot	23.5	61.8
2 feet	14.7	40.4
4 feet	9.6	23.6
8 feet	2.7	7.4
12 feet	1.0	2.7
20 feet	0	0

The foregoing data show that approximately fifty per cent of the temperature rise in the earth occurred under these conditions within a distance of one and a half feet from the pipe.

Another phase of the temperature survey, one that has been continued for a number of years, is concerned with ground temperatures that prevail at Detroit during the different seasons of the year at various levels below the ground surface. These temperatures were determined at the location of the experimental installation at a distance of 21 feet from the pipe, that is, in ground that is unaffected by the operation of the experimental cable installation. Pertinent data obtained in this study at the same location and at the same time of the year were averaged for three successive years, and were used in the curves of Figure 10.

Figure 7. Time-temperature characteristics of shielding tapes of cables type G, H, and I, at time of shutdown and resumption of load

Soil Resistivity

Data concerning resistivity values of several types of soil have been collected during the past several years. Cylindrical cells of the type shown in Figure 4, equipped with voltage regulating devices, have been installed. Close regulation of the supply circuit, as well as the use of the maximum permissible current, considerably reduced the percentage of error and fluctuating readings. The data obtained with these cells were introduced into the following formula in order to obtain the thermal resistivity of the soil:

$$\rho = \frac{128}{W}(T_1 - T_2)$$

where

ρ = thermal resistivity of soil, degrees centigrade per watt per centimeter cube

W = watts dissipation, watts

T_1 = temperature of cylinder wall, degree centigrade

T_2 = temperature of ambient earth, degree centigrade

This formula is empirical and was

Table V. Summary of Pertinent Data Obtained from Measurements on the Experimental Line (Continued)

derived by comparison of the results obtained with such a cylinder and those obtained with a sphere.[5] Test results obtained at each location during several years have been averaged to eliminate radical variations, and pertinent results are shown in Figure 11. In only one case (in yellow clay) has a "run-away" condition occurred in the resistivity value (not shown). In that case a dissipation of 50 watts from the one-foot long, 3-inch diameter cell resulted in the cell temperature increasing from 58.9 to 82.2 degrees centigrade within nine days during which time the ambient temperature was essentially constant. This caused a drying out of a 1/2 inch layer of earth. A curve of resistivity prevailing at one location along the commercial pipe line is also included in Figure 11. This curve was constructed from data obtained by means of measurements made on the commercial line. The thermal resistance calculated from data of temperature drop from pipe covering to ambient and of watts dissipated was introduced into the following formula in order to obtain the thermal resistivity.

$$R_{th} = \frac{\rho}{2\pi} \log_e \left[\frac{4l}{D}\right]$$

where

R_{th} = thermal resistance of soil, in watt–centimeter units

ρ = thermal resistivity of soil, in watt–centimeter units

l = distance below surface of earth of axis of buried pipe, in inches

D = outside diameter of pipe, including protective covering, in inches

The following tabulation shows the relationship between the resistivity as determined from the experimental cable line in a similar manner and a soil resistivity cell which was in operation nearby:

Test	Thermal Resistivity C/W/Cm²: Experimental Line	Soil Cell
1	46.5	61.0
	53.8	61.0
2	51.6	64.0
	49.7	64.0
3	52.5	74.0
Average	50.8	64.8

The foregoing results show the soil cell data to be consistently higher than those determined from the experimental line and therefore such data may be safely used for current rating calculations. In general, the resistivity values have not been found to correlate to precipitation, cloudiness, or transient temperature fluctuations. Lower readings appear prevalent in late winter. In summer, they are somewhat higher. Presumably the pipe and cells are deep enough in the earth so that rainfall is substantially uniformly distributed in time and space before reaching them.

In connection with determination of the soil resistivity, moisture determinations have been made from time to time in various locations. The moisture content of the soil obtaining at the time when data for test 3 in the foregoing table were being procured, and in the same location ranged from 12.8 to 21.1 per cent, with an

Figure 8. Long time cooling curves

Cables type G, H, and I

Figure 9. Temperature distribution through earth

Cable section *A*

Figure 10. Ambient earth temperatures

average value of 17.3 per cent for nine determinations. An effort was also made to determine the moisture distribution for various distances from the pipe, ranging from 6 inches to 25 feet. Little information has been obtained to date, but the results indicated that the moisture content decreased as the distance increased to $2^1/_2$ feet and remained essentially constant for the rest of the distance investigated. At a distance of six inches the moisture content was 19.9 per cent, at $1^1/_2$ feet it was 18.2 per cent, and from $2^1/_2$ feet to 25 feet it remained essentially constant at 17.1 per cent. The type of soil changed from fine cinders, sand, and tan clay at the six-inch distance to tan and gray clay as the distance was increased.

Surface Resistivity from Pipe to Air

One of the items the cable engineer must consider is the operating temperature of the cable line in air at such locations as terminals, canal crossings, and so forth. The data in Table V which give a summary of pertinent results obtained in the field, show under test 1 that the conductor temperature in the terminal $3^5/_8$-inch riser pipe was five degrees lower than that of the cable operating in the seven-inch pipe buried in the ground and under the same loading conditions.

Tables II and III include data of the surface resistivity values obtained on the pipe used in the laboratory tests. The resistivity was found to vary from 690 to 870 with an average value of 774 degrees centigrade per watt per square centimeter. Insulated Power Cable Engineers Association recommends 1,200 for diameters over 1.75 inches whereas the foregoing results show that for a bare pipe in air (and presumably also for a pipe in air with a protective covering of type *A*) it would be safe to use a value of 850 degrees centigrade per watt per square centimeter provided the pipes were shielded from the sun or were installed indoors.

A portion of the commercial pipe line with type *A* coating is exposed to free air outdoors where it crosses the intake canal for the Delray Power House. Numerous temperature measurements were made at this location and some of the results are shown in Table VI together with related information concerning loading and weather conditions. Inasmuch as the load carried by the line during these measurements was reasonably constant, the pipe temperature changes as shown are a direct function of atmospheric conditions.

Table VI. Average Temperature Rise of Commercial Pipe Line Over Intake Canal During Various Seasons of the Year

Month	Air Temperature, °C	Sunshine, Per Cent*	Average Wind Velocity,* Miles Per Hour	Relative Humidity,* Per Cent	Average Load, Watts Per Foot of Pipe	Measured Average Rise Above Ambient, °C
January	4.3	16	11.1	66	11.0	4.2

Thermal Resistivity of Pipe Coverings

Regarding the thermal resistivity of type *A* pipe covering composed of asphalt, asbestos, sand and mineral filler, the field tests yielded an average value of 263 degrees centigrade per watt per centimeter cube. This is equal to a conductivity of 2.68 Btu per hour per square foot per degree Fahrenheit per inch of thickness. Results of laboratory tests in which slabs of the material were used gave values of 7.75 to 7.90 with an average of 7.83 for the conductivity. The field tests resulted in higher thermal resistivity values possibly because of imperfections in the bond between the pipe and the covering that might have existed at the location where the measurements were made. Inasmuch as temperature measurements were made at the pipe surface and the outer surface of the covering, an air space between the pipe and the covering would result in higher calculated values of thermal resistivity.

The resistivity of type *D* pipe covering consisting of two acetate membranes and a concrete envelope of a minimum thickness of three inches was found to have an average value of 71.5 degrees centigrade per watt per centimeter cube. This is equal to a conductivity of 9.7 which is about the maximum that one would expect for concrete. There were no provisions made for obtaining thermal resistivity data in the field for the pipe coverings of types *B* and *C*.

CALCULATIONS

Three-Phase D-c Conductor Loss

$X - 477^2 \times 0.01428 = 3,250$

$Y - 455^2 \times 0.01351 = 2,800$

$Z - 468^2 \times 0.01357 = 2,970$

Total I^2R loss $= 9,020$ watts
Total a-c loss $= 12,000$
Extra a-c loss $= 12,000 - 9,020 = 2,980$

$$\frac{\text{Extra a-c loss}}{\text{D-c Conductor loss}} = \frac{2,980}{9,020} \times 100 = 33 \text{ per cent}$$

Single-Phase D-c Conductor Loss

$X - 621^2 \times 0.0148 = 5,710$

$Z - 621^2 \times 0.0148 = 5,710$

Total I^2R loss $= 11,420$ watts
Total a-c loss $= 14,160$
Extra a-c loss $= 14,160 - 11,420 = 2,740$

$$\frac{\text{Extra a-c loss}}{\text{D-c Conductor loss}} = \frac{2,740}{11,420} \times 100 = 24 \text{ per cent}$$

Note: Data are for cable with 600,000-circular mil, concentric round conductor and 600 mils of insulation lying along the contour of a 7-inch outside diameter steel pipe.

kv experimental line, it is shown that the thermal surface resistivity, from the cable surface to the inner wall of the pipe, for the *SMD* 400,000-circular mil cable varied from 132 to 350 with an average value of 229 degrees centigrade per watt per square centimeter. This is somewhat lower than the laboratory value of 400 which is an average of the values given in Table III. In the case of the *SMD* 600,000-circular mil cable the variation was found to be from 162 to 376 with an average of 286, which is again lower than the 553 value of Table II obtained in the laboratory test using the 750,000-circular mil conductor with 500 mils of insulation.

In computing the values, the surface area was taken to correspond to that of a cylinder having a diameter equal to 2.155 times the diameter over the shielding tape of an individual cable.

In the laboratory tests a six-inch inside diameter pipe was used and the conductors were held in a triangular configuration. On the experimental line a seven-inch outside diameter pipe is used and the cables lie along the contour of the pipe. The fact that position of the cables in the pipe has an appreciable effect on the surface resistivity from cable to pipe has been shown in the laboratory tests already discussed. This effect of position is probably brought about in some measure by differences in the contact between the outer surface of the cable (in some cases copper skid wires) and the inner surface of the steel pipe. Also, the position of the cables in the steel pipe might have an appreciable effect on the heat transfer by convection. In a paper by Whitehead and Hutchings[6] it is pointed out, for instance, that the convection loss for a cable lying on the bottom surface of a duct is 30 per cent lower than that for a cable that is in a concentric position with respect to the duct when the ratio of cable diameter to duct diameter is 0.5. The probability that heat transfer by convection has a considerable bearing on the value of surface resistivity from the outer surface of the cable to the inner surface of the pipe was indicated in the laboratory tests in which the effect of gas pressure was studied. The fact that a definite increase in resistivity with decrease in gas pressure was found cannot be explained by a change in heat transfer by conduction, since the thermal conductivity of a gas does not change for pressures in this region. It is also well known that gas pressure has no measurable effect on the heat transfer by radiation. This leaves us the only possibility changes in the heat transfer by convection. That heat transfer by convection increases with the density (pressure) of a gas is shown, for instance, by Jakob and Hawkins.[7]

The preceding results show that a value of 500 may be safely used for high-pressure gas-filled cable while the laboratory tests suggest 400 for high-pressure oil-filled cable as a fair working basis for current rating calculation.

Figure 12. Power factor versus temperature, at 70 kv

Thermal Resistances–Conductor to Sink

Perusal of the data given in Table V for the purpose of determining the percentage contribution of the four elements constituting the total thermal path from each conductor to sink yields the following values:

Thermal Path	Average Thermal Resistance Ohms/Ft/Conductor	Per Cent of Total Resistance
Insulation	2.48	42.7
Gas medium	.78	13.4
Pipe covering	.48	8.3
Earth	2.06	35.6

Increase in Losses Due to the Steel Pipe

One of the problems in determining conductor sizes for new projects or thermal constants on existing pipe-type systems is the matter of a-c/d-c losses. Section *A* of the experimental line provided an excellent opportunity to check these losses for three cables with 600,000-circular mil, concentric round conductor and 600 mils of insulation lying along the contour of a 7-inch outside diameter steel pipe. The results of such measurements are shown in Table VII.

It was found that the ratio of all a-c loss effects to the conductor d-c loss amounted to 33 per cent for 3-phase operation and 24 per cent for single-phase operation for the particular geometric arrangement used in this test.

Power Factor Measurements

Inasmuch as many of the calculations to determine the thermal characteristics were based on conditions during which the cable was subjected to a potential of 120 kv (69.4 kv to ground), it was necessary to know the dielectric loss pertaining to that condition, and a considerable number of power factor measurements were made for that purpose. Figure 12 is included to give some of the results obtained during power factor temperature determinations made at 70 kv on cables of types *G*, *H*, and *I*, at the end of a sustained run at a conductor temperature of approximately 100 degrees centigrade.

Appendix I. Description of Protective Pipe Coverings

Type *A*

An asphalt-mastic compound composed of asphalt, asbestos, sand and mineral filler. It was extruded on the pipe, hot, to a thickness of 7/16 inch and weighs 135 pounds per cubic foot.

Type *B*

A plasticized coal-tar enamel, including two layers tar asbestos felt, with an exterior layer of Kraft paper.

Type *C*

A hot application of an adherent coating of wax, chemically and mechanically fortified, a spiral wrapping of reinforced asbestos, a hot application of a service coat incorporating natural asphalt, a spiral layer of a single membrane wrapper, and a spiral wrapping of heavy Kraft paper.

Type *D*

The pipe was coated, previous to installation, with two acetate membranes, applied with hot wax. Concrete was then poured around the pipe, in the trench, to a minimum thickness of three inches.

Appendix II. Description of Cable Constructions Used in the Experimental Line

Type *A*. *SMD* Cable (Experimental—Manufactured Without Humidity Control)

One-conductor 600,000-circular mil, concentric round, 600 mils preimpregnated paper, bronze tape intercalated with saturated cotton tape, cotton webbing tape lapped. Cable shipped with temporary lead sheath.

Type *B*. Compression Cable (Unarmored)

Three-conductor type *HSL*, 650,000-circular mil, Compack oval, 500 mils mass-impregnated paper, 85 mils lead, three saturated manila tapes butted, two bronze tapes butted, two saturated cotton tapes intercalated, two saturated cotton webbing tapes intercalated. Separately insulated and lead covered single conductor cables with outer protective coverings were cabled without fillers or outer binder. During installation the lead sheath of one conductor was perforated with holes approximately 1/8-inch diameter at 25-foot intervals.

Type *C*. Compression Cable (Armored)

Three-conductor type *HSL*, 650,000-circular mil, Compack oval, 500 mils mass-impregnated paper, 85 mils lead, three saturated paper tapes butted, two bronze tapes butted, two saturated cotton tapes intercalated. Separately insulated and lead-covered single conductor cables with outer coverings cabled with saturated jute fillers and covered with saturated duck tape, 5/64-inch jute bedding and one layer number 8 Birmingham wire gauge steel wire armor.

Type *D*. *SMD* Cable (Experimental)

One-conductor 400,000-circular mil, Compack round, 400 mils preimpregnated paper, copper tape intercalated with saturated cotton tape, cotton webbing tape lapped, two half-round skid wires 200 by 100 mils applied open spiral. Cable shipped with a temporary lead sheath.

Type *E*. *SMD* Cable (Experimental)

Similar to type *D* except with 450 mils preimpregnated paper.

Type *F*. *SMD* Cable (Experimental)

Similar to type *D* except with 500 mils preimpregnated paper.

Type *G*. *SMD* Cable (Commercial, 1941 Warren-Delray Circuit)

One-conductor 600,000-circular mil, concentric round, 600 mils preimpregnated paper, bronze tape intercalated with saturated cotton tape, cotton webbing tape lapped, two half-round copper skid wires 200 by 100 mils applied open spiral. Cable shipped with temporary lead sheath.

Type *H*. *SMD* Cable (Experimental—Mass-impregnated)

One-conductor 600,000-circular mil, Compack round, 600 mils mass-impregnated paper, two copper tapes intercalated, 2 half round copper skid wires 200 by 100 mils applied open spiral. Cable shipped on weathertight reel with dry nitrogen.

Type *I*. *SMD* Cable (Experimental—Mass-impregnated)

One-conductor 600,000-circular mil, Compack round, 500 mils mass-impregnated paper, copper tape intercalated with polyethylene tape, two copper tapes intercalated, two half-round copper skid wires 200 by 100 mils applied open spiral. Cable shipped on weathertight reel with dry nitrogen.

Type *J*. *SMD* Cable (Experimental—Mass-impregnated)

Similar to Type *I* except with 400,000-circular mil, Compack round conductor and 400 mils mass-impregnated paper.

Note: Strand and insulation shielding used on all cables.

Discussion

R. J. Wiseman (The Okonite Company, Passaic, N. J.): We owe a vote of thanks to the authors for their paper dealing with the thermal characteristics of a pipe system. I look upon the paper as broader in nature than applying particularly to a gas-filled cable installation, as the data presented for the external thermal field is applicable to all kinds of buried cables. Also, they give some thermal constants for the internal field for a gas pressure system which can be compared to oil pressure systems. The transient temperature section is quite helpful in appreciating what overloads can be carried on a buried cable.

The considerable amount of data which is reported in the paper will require a long study to properly appreciate. Table II gives a comparison between the cable assembly using gas and oil as the pressure medium. We would expect the oil to give lower thermal constants. For the insulation, we have been taking 550 thermal ohms per centimeter cube for the gas set-up, and 450 for the oil. Is it possible that because the oil tests were made after the gas tests that the insulation had not reached complete saturation at the time the oil tests were made? For the gas zone and 200 pounds per square inch, we use the formula $R_{th}=2.06N/CD$, where N is the number of conductors, and CD is the circumscribed diameter over the insulated cables assumed to be assembled in a triangular arrangement. The constant 2.06 is equivalent to a surface resistivity of 500 thermal ohms per centimeter square, whereas the authors report a value of 553. I am inclined to believe their value is influenced by the canvas tape wrapped over the copper shielding tape. Taking the foregoing formula, we get a thermal resistance of 1.40 thermal ohms per foot without considering the canvas tape, whereas they get 1.41 thermal ohms per foot. For the oil zone, we assume the cylindrical log law for calculating the thermal resistance, the diameters being the inside diameter of the pipe and the circumscribed circle around the insulated conductors. The thermal resistivity was determined by test and is a function of temperature, as this affects the convection of oil. The thermal resistance computed by us would be about 40 per cent of the value given for the oil tests in Table II. In the case of oil, we have viscosity, convection, and conduction as influencing factors for the thermal resistance. The authors state that they used 700-second oil for the pressure medium. The difference in thermal resistance for our computed value and what they get can be explained on their using a much higher viscosity oil, which greatly affects the apparent thermal resistivity. For example, we use a value of 110 thermal ohms per centimeter cube for a conductor temperature of 70 degrees centigrade, and a value of 180 when the conductor temperature is 45 degrees centigrade. The respective viscosities are in the ratio of four to one. We have found the surface resistivity from pipe to air the same as reported in Table II, namely, about 850 thermal ohms per centimeter cube.

Table III, showing the influence of the position of the cables in the pipe, is a bit puzzling. In the original position, the surface resistivity for cable to pipe shows the lowest value and for pipe to air, the highest. Why should pipe to air be influenced by what is happening inside the pipe? Also, what caused the variation for cable to pipe? The shielding tape temperatures were closely the same for all positions, but the pipe temperature varied. Was there a breeze which might have cooled the pipe for the 120 degree, 240 degree positions, and second original position? Were the cables so placed in the pipe that on rotation they might have become suspended in the pipe?

Figure 9 showing the temperature distribution from the surface of the pipe to a point 20 feet away is very instructive. As the authors state, 50 per cent of the temperature rise occurs within 1.5 feet of the pipe. Some of us wonder why we take the law of images in computing the thermal resistance for a buried cable or pipe and not a cylindrical shaped field having a radius say 10 times the diameter of the cable or pipe. All but a very small percentage of the temperature rise will fall within it, and we can neglect the earth outside it, which rises in temperature very slowly so actually does not greatly influence the total rise.

The need for a better understanding of the shape of the thermal field around a buried cable in pipe and the proper formula to use to calculate the thermal resistance is brought out in the paper, where a comparison of the thermal resistivity of the earth is computed from a soil cell and also the experimental line, using the law of images formula for the latter. I feel that some of the difference is due to the assumption which we all take that the law of images formula applies. Some of us are questioning it. A study of Figure 5 is worthwhile, as it shows how the temperature at points K, H, and N, which are 2 feet from the pipe, are closely the same, indicating a cylindrical field condition, rather than one based on the law of images.

Figure 11 showing the variation in soil thermal resistivity monthly for a year is quite interesting. Although there is an indication of an increase during the summer months, the magnitude is not very great, and it is safe to take an average value independent of time of year without serious error. The statement regarding the change in moisture content of the soil with depth is very helpful. As we normally bury the pipes at least 3 feet, it means we can expect fairly constant soil conditions. This may account for the small variation in soil thermal resistivity shown in Figure 11.

This paper is going to be very helpful to the insulated conductor committee of AIEE, which is studying this earth thermal resistance problem. It is not an easy one, as there are so many factors involved. However, in time, we can hope for a clearer understanding of what takes place and how to take care of it.

C. T. Hatcher (Consolidated Edison Company of New York, Inc., New York, N. Y.): Sanderson, Sticher and McGrath have made a very valuable contribution to the data required for determining ratings of pipe cables. Their data on earth thermal resistivity is very valuable since this has been a very controversial subject and requires settlement if over-all economy is to be obtained on underground systems.

We are conducting tests somewhat similar to those described in the paper. A test cell and an experimental length of pipe have been installed in our Queens district and over a period of approximately a year's operation the following values obtained.

Experimental Pipe	53 C/W/CM^3
Soil Cell	68 C/W/CM^3

From data obtained from a heat run on the Jamaica–Valley Stream 138-kv pipe line we obtained a value of 55 to 65 C/W/CM^3.

It is stated that the ratio of all a-c loss effects to the conductor d-c loss amounted to 33 per cent for 3-phase operation and 24 per cent for single phase operation. From tests made with three 350,000-circular-mil 138-kv cables in a 6 inch outside diameter pipe we found that for 3-phase operation the following values were obtained; $19^1/_2$ per cent at 30 degrees centigrade $17^1/_2$ per cent at 55 degrees centigrade.

C. T. W. Sutton (Enfield Cables Limited, Brinsdown, Enfield, Middlesex, England): The most interesting information gleaned from the data given in the paper are the thermal resistivity values actually computed from the results of tests, especially those suggested for the pressure medium.

In the early stages of the development of the compression cable system many investigations of similar character to those described were undertaken both here in Britain and on the continent of Europe and it is pleasing to find that the results we originally obtained are of the same magnitude as those now given.

We considered that it was of sufficient accuracy to assume a fixed thermal resistance value for the gas in the pipe irrespective of conductor size or dimensions of pipe and not to attempt to calculate the value for individual cases, especially as the thermal resistance of the ground, always an uncertain quantity, constitutes the major portion of the total resistance. Thermal resistivities of the gas calculated from temperature reading can only be valid for a particular set-up because the relative influences of conduction, convection and radiation vary.

We found that the configuration of the cable construction had a marked effect on the thermal resistance of the gas space and from the results obtained by several investigators the following thermal resistances were used for the current rating determinations.

1. 3 core screened	20 degree centigrade per watt per centimeter or 0.66 degree centigrade per watt per foot
2. 3 single core cables	10 degree centigrade per watt per centimeter or 0.33 degree centigrade per watt per foot

This confirms the variations in the thermal resistances that were noticed when the pipe was rotated through 120 degrees, especially as it appears from the information given in Table III that these particular tests were conducted with three cables of different dimensions enclosed in the same tube.

Values as low as 400 degrees centigrade per watt per centimeter cube for the resistivity of the dielectric of compression cables with normal gas pressure have been measured but for calculations of current

rating a value of 500 is assumed, while for gas-filled insulation a figure of 750 has been agreed.

The pipe covering type *A* given in Appendix I appears thick and figures are not given for types *B* and *C*. We have found from several years of operating experience that adequate protection against corrosion, electrolytic or otherwise, can be guaranteed by coating the pipes with the rubber sandwich protection (British Patent number 425906) which when applied by machine has a radial thickness of approximately $^5/_{16}$-inch and consequently its thermal resistance is very low, that is, in the region of 0.13 degree centigrade per watt per foot for a resistivity value of 500.

Referring again to Table III, is it not possible that the thermocouple readings were correct for the cable with the 500 mil dielectric thickness, because impregnated paper has a conductivity of seven times that of the gas, although the margin would of course be reduced due to convection and radiation in the gas space, especially convection.

The following thermal resistance values are typical of those used for obtaining current rating data for compression cables.

Cable: 0.5 Square Inch, 3-Core "S L", Pipe-Line Type 132-Kv, 3-Phase Working Pressure

	Thermal Resistivity °C/watt/cm²	Thermal Resistance °C/watt/cm	Per Cent
Dielectric thickness, 0.40 inch	500	50.5	
Diaphragm sheath reinforcements			
Oiled papers	750	1.1	
Oiled cotton tapes	500	1.3	
3 Cores in parallel	17.6		18.5
Gas	10		10.5
Pipe protection			
Rubber sandwich, Thickness 0.145 inch	500	3.7	4.0
Soil—depth 42 inches to top of pipe	120	64	67
Total		95.3	100

Finally it was interesting to note that electrical failure considered the result of faulty registration of the papers, or moisture occurred in types *A* and *D* cables at a stress of 264 volts per mil which corresponds to 10.6 kilovolt per millimeter. This is not an unduly large value for the stress especially as compression cables are working at stresses as high as 150-kilovolt per centimeter. These figures clearly show that cable designs containing gas pressure in the active dielectric are always liable to fail due to manufacturing weaknesses, as the factor of safety is not extremely high.

J. H. Neher (Philadelphia Electric Company, Philadelphia, Pa.): The thermal resistances involved in the determination of the temperature-rises in pipe-type cable systems depend upon so many interrelated variables that it is impractical to completely cover all possible combinations which may be met in practice by test. For this reason some of us have been actively endeavoring to establish formulas by which these resistances may be calculated.

While this development is based primarily on theory, the resultant formulas must be co-ordinated with such tests as are available, and to this end the very complete data presented by the authors will be of very great benefit. Since I have not had a chance to examine these data prior to this meeting, my remarks here must be quite general.

I note that the authors indicate a figure of about 850 degrees centigrade, square centimeters per watt, as the surface resistivity of the pipe in air, and compare this figure with that of 1,200 given by the Insulated Power Cable Engineers Association. To understand the mechanism of heat transfer involved, one must think in terms of conductance rather than resistance, and realize that this conductance is composed of a convection and a radiation component. The radiation component is dependent directly upon the surface emissivity constant, which is highest for a black painted surface. It so happens that the figure of 850 agrees not only with the theoretical value for a black pipe of this size but also with such other test results as I have observed. The figure of 1,200, on the other hand, is presumably based on a tarnished lead sheath where the emissivity is about half that of the black pipe, resulting in the correspondingly higher value of resistance.

In the case of the heat flow between cable surface and the pipe, there is an additional conduction component which must be added to the convection and radiation components. The way in which these components will vary and their relative effect on the over-all conductance will depend upon the type of medium filling the intervening space. Thus when the medium is oil, the radiation component is relatively insignificant and the convection component will vary as the 3/4 power of the oil temperature. If the medium is gas, the conduction component is relatively small and the convection component now varies theoretically as the square root of the absolute pressure.

Finally, the authors have indicated an observed value of roughly 50 degree centigrade, centimeters per watt, for the thermal resistivity of the earth by back calculation from the cable tests as contrasted with about 65 as observed by a test cell installed at the same location. This apparently large discrepancy may be due to the fact that the temperature-rise of the cable system had not reached its ultimate value at the time of the observation. Due to the very long temperature-time transients involved, it is often impossible to establish the ultimate temperature-rise by merely plotting the temperature-rise against time with rectangular co-ordinates. We have found the following procedure to be more advantageous in this connection.

The measured temperature-rise per watt per foot $\Delta T/Q$ is plotted against time on log-log paper. The theoretical temperature-time transient, which may be obtained with sufficient accuracy from an equation given in the Whitehead and Hutchings paper cited by the authors,[1] is similarly plotted on a sheet of the same log-log paper, plotting $\Delta T/Q\rho$ against te/r^2 where ρ and e are the thermal resistivity and diffusivity of the earth respectively, and r is the radius of the pipe. The two sheets are then superimposed and the best match is obtained with the upper portion of the measured curve keeping the axis of the sheets parallel. The relative positions of the axis of the two sheets will then give ρ and e/r^2 directly. Since r is known e is readily determined.

A. D. Petzee (General Cable Corporation, New York, N. Y.): It is worthwhile to point out in Figure 12 of the paper the difference in power factor between cable *G* and cables *H* and *I*. All three cables were impregnated with synthetic oil with a viscosity of 3,000 Saybolt Universal seconds at 100 degrees centigrade.

Cable *G* was insulated with predried preimpregnated tapes in an atmosphere kept below a specified relative humidity, whereas cables *H* and *I* were taped dry and mass-impregnated as with a solid type cable, which permits drying and impregnation of the insulation after taping, and without exposure to the air.

While the power factor of the preimpregnated tape cable is adequately low, the power factor of the mass-impregnated cable is inherently lower and permanently so on account of its lower moisture content.

These experimental cables, by the way, represent the first public use of high voltage cable mass-impregnated with a compound of viscosity 3,000 Saybolt Universal seconds at 100 degrees centigrade, which is 20 to 30 times that used with "solid" cable.

W. D. Sanderson, J. Sticher, and M. H. McGrath: The authors are very much pleased with the interest shown in this paper and wish to thank the engineers who have submitted discussions. In general, these discussions confirm the data presented. Wiseman takes the results shown in Table II to be representative of a cable assembly using gas and oil respectively as the pressure medium. This particular investigation was concerned with the heat flow through the compression medium, and other data which were readily obtained during the test were included in the table.

Inasmuch as the cable used in this particular phase of the investigation was of the "solid" type, the resistivity value, shown for the insulation cannot be considered to be strictly representative of both the gas and oil-filled systems. However, the results obtained for the insulation with gas as a pressure medium are quite close to those obtained with the actual *SMD* cables as shown in Table III. Concerning the results obtained with oil as a pressure medium, it must be pointed out that the likelihood of incomplete insulation saturation seems extremely unlikely because in both the 100 and 200 pounds per square inch tests, the setup was held at approximately 70 degrees centigrade for more than four hours. At these pressures and at this temperature, complete saturation of the insulation with an oil having a viscosity of 700 seconds at 100 degrees Fahrenheit should be effected in a fraction of this time.

Sutton mentions that in England a figure of 750 has been agreed on for gas-filled insulation. In 1942 Beaver[1] reported a value of 700. The average thermal resistivity of low pressure (9–15 pounds per square inch gauge) gas-filled insulation has been given as 700 by Shanklin.[2] Inasmuch as the insulation of both the Beaver cable and the

low-pressure gas-filled type is impregnated with a saturant which has a viscosity at 100 degrees centigrade of only three to five per cent of that used in the gas-filled cables listed in Appendix II of the paper, it seems reasonable to expect the loss of saturant from the paper fiber in process and in service to be materially lower for these latter cables particularly as, in addition, a relatively large portion of the insulation wall is composed of superdense and high density paper. It is believed that this is also the explanation for the relatively low thermal resistivity of the gas-filled cable designs used in the tests described in the paper.

Permanency of the initially-low thermal resistivity is indicated by the absence of any significant change in the specific inductive capacity after the experimental field runs or after severe drainage tests. In this connection it is pertinent to note that, while Beaver reports a permittivity of 2.9 to 3.0 for the English gas-filled cable, the gas-filled types of cable listed in Appendix II have permittivities very closely the same as for a "solid" or low-pressure oil-filled cable with substantially the same tape structure.

Sutton wants to know if it is not possible that the loose thermocouple on the 500-mil sample of Table III gave correct results and goes on to explain the well known fact that dry paper fiber has a lower thermal conductivity than impregnated fiber. As pointed out before, the paper fiber in question is impregnated and remains so in service. It is not clear as to just what Sutton is attempting to prove because he seems to have overlooked the fact that the measured conductor temperatures on the 500 mil with the loose thermocouple were lower than expected, which means that if the values had been accepted as correct, the calculated thermal resistivity would have been lower, not higher, than given in Table III.

Sutton gives a tabulation of a set of thermal resistivity values and typical thermal resistances (it might be pointed out, for the sake of the record, that in the tabulation the heading of the second column of figures should be thermal resistance) for a 0.5-square-inch compression cable with 400 mils of insulation; the dimensions of the pipe are not given. It is interesting to note, however, that if Sutton had employed a soil resistivity of 50 (which value approximates that indicated in the test runs covered by Table V) the total thermal resistance from conductor to soil ambient for Sutton's compression cable would be within two per cent of that given in the section of the paper captioned "Thermal Resistances—Conductor to Sink." Sutton does not mention any correction for the sheath losses in the compression cable. If these sheath losses would be included Sutton's compression cable would have a greater temperature rise from conductor to sink, and, consequently, a lesser current rating for the same soil resistivity.

The rubber sandwich-type of pipe corrosion protection mentioned by Sutton was considered here some years ago but was not employed because of its relatively high cost. It should be noted that the thermal resistance figure of 0.13 degree centigrade per watt per foot of circuit given by Sutton for a 3/16-inch covering is 0.39 degree centigrade per watt per foot of conductor. The latter value is not materially different from the 0.48 value given in "Thermal Resistances—Conductor to Sink," section of the paper for a 7/16-inch covering.

It is interesting to note that Wiseman's calculations of the thermal resistance across the gas zone, using 500 as the surface resistivity, is practically identical to that obtained from the test results. However, he states that his calculated thermal resistance across the oil zone would be only 40 per cent of the value obtained from the test with oil as the pressure medium. Wiseman expresses the view that this is due to the use of an oil having a higher viscosity than that which his computed results would apply. The oil used was supplied by the Okonite-Callender Cable Company and was known as Oilostatic oil or 700-second oil. Since Wiseman's calculations are based upon a surface resistivity which was determined by test, it would be very helpful if Wiseman would present this data on the thermal characteristics of Oilostatic-type cable in the near future. In all the laboratory tests conducted by the authors, the surface resistivity values obtained have never approached the low values reported by Wiseman.

The variation in the surface resistivity from cable to pipe as shown in Table III was due to the changes in the geometric arrangement of the cables with respect to the pipe, resulting from the rotation of the assembly. The cables were bound in a triangular configuration before being placed within the pipe. This allowed the various cables to become suspended in the pipe as the assembly was rotated. It was interesting to learn that Sutton's investigation confirmed the variation found in the surface resistivity from cable to pipe.

Sutton states that it is sufficiently accurate to consider the thermal resistance from cable surface to pipe wall through the gas medium as a constant irrespective of cable dimensions. For three single conductor cables in pipe Sutton suggests a constant value of 0.99 degree centigrade per watt per foot of conductor. We cannot subscribe to Sutton's point of view because reference to Table III shows that his proposed constant is from 11 to 97 per cent below the measured values. Sutton argues that accuracy is not required in this term because it is small with respect to the earth term. However, he apparently uses a soil resistivity of 120 whereas in this country 70 to 80 is customary. For example, if one should assume that he in his tabulation, had underestimated the thermal resistance from cable surface to pipe by 100 per cent, then for a soil resistivity of 80, his final rating would be approximately seven per cent high.

Wiseman and Neher have commented on the surface resistivity from pipe to air. In this connection it should be recalled that this particular investigation was undertaken to study the thermal characteristics of the path through the pressure medium as affected by the position of the cables in the pipe. Here again, other data that were readily obtained were included, such as those covering the heat flow from the pipe surface to air. One explanation of the variations mentioned could be that the welding generators used to provide the necessary direct current had built in fans for cooling and it is very likely that these, along with the building air-conditioning system, could have set up a breeze to cool the pipe assembly.

We were very pleased to learn that Hatcher's soil resistivity data confirmed those obtained in Detroit and that he will continue tests along this line. We are looking forward to early publication of the results. With respect to Neher's comment on the back calculations of soil resistivity and long-time transient effects, an alternate and somewhat simpler approach to the transient problem is to employ the solution for a continuous line source of constant strength. On this basis the long-time transient thermal resistance from the surface of the covering to earth sink with constant load may be written as:[3]

$$R_{(t)} = \frac{\rho}{2\pi}\left[\log_e \frac{4l}{D} - \frac{1}{2}(F(V') - F(V))\right]$$

where the symbols and units except for those indicated below, are the same as given in the text.

$$V' = \frac{(2.54)^2 l^2}{\xi t} \qquad V = \frac{(2.54)^2 D^2}{16 \xi t}$$

ξ = thermal diffusivity in cm²/sec
t = time of application of constant load in seconds

$$F(x) = x - \frac{x^2}{2 \times 2!} + \frac{x^3}{3 \times 3!} - \frac{x^4}{4 \times 4!} + \ldots$$

For values of x above 3.0, $F(x)$ may be computed from $F(x) = 0.577 + \log_e (x)$.

The attainment factor or the ratio of the pipe covering surface temperature rise (above ambient at depth of burial of pipe axis) at time "t" to the ultimate temperature rise is then:

Attainment factor

$$= 1 - \frac{(F(V') - F(V))}{2 \log_e \frac{4l}{D}}$$

Gemant and Sticher[4] have made a careful estimate of the diffusivity of soil in the vicinity of the experimental line for soil having a resistivity of 72 as determined by the soil cell. Considering a run such as test period 8 where the time under constant load was of the order of 1,000 hours and using the Gemant and Sticher estimate of 4.2×10^{-3} centimeter square per second for the diffusivity, it is found that for a 54-inch depth and a covering diameter of 7 7/8 inches $V' = 1.25$, $V = 1.7 \times 10^{-4}$, $F(V') = 0.94$, $F(V) = 0$, and $2 \log_e \frac{4l}{D} = 6.6$. Hence the attainment factor is 0.86. This means that if the ultimate resistivity were 72, the apparent value at the end of 1,000 hours would be 62. It is interesting to note that the ratio of soil cell to line resistivities as given in the tabulation in the paper is 0.79. This consideration shows that values derived from the cable test are about 14 per cent too low; the true value appears to lie between those derived from the cable and from the cell.

The foregoing method could also be used to determine ultimate resistivity and diffusivity directly from measured values of temperature rise and time on the line pipe by use of simultaneous relationships.

Wiseman's comments on the soil temperature data in the vicinity of the loaded pipe recalls the assumption proposed by Apt[5] some years ago. Apt suggested that as a first approximation the effect of the earth surrounding the cable could be con-

sidered to be equivalent to that of a cylinder of material having a thermal resistivity equal to that of the soil and having a radius equal to the depth of the cable axis below the surface of the ground. This assumption was considered by the British[6] in 1923 but was not adopted by them because an experimental investigation on the effect of depth of burial showed the Kennelly assumption to more nearly represent the observed facts.

Hatcher's supplemental information concerning the ratio of all a-c loss effects to the d-c loss was welcomed by the authors. Further work needs to be done on this particular phase of the pipe-type system in order to be able to break this extra loss up into its components. In preparing Table V, 61 per cent of this extra loss was considered to be in the iron and the remaining 39 per cent to be additional conductor loss. We are aware that the above percentages are not absolutely correct, but they do give thermal constants which are slightly on the conservative side.

The authors appreciate the comments by Pettee who is associated with one of the authors. This information is additional to that given in the paper, and might well have been included in it. However, an attempt was made to limit information as much as possible to that more closely related to the thermal characteristics of the cable installation.

Sutton's assumption that the electrical failures in the type *A* and type *D* experimental cables were the result of faulty registration is incorrect. As clearly indicated in the paper, the failure on the type *A* cable, which was the first experimental *SMD* cable ever made, occurred during overload tests in connection with thermal studies, as the result of cumulative dielectric loss due to moisture absorbed during manufacture with preimpregnated paper tape applied in open room air without humidity control of any kind. The importance of such control was appreciated fully at the time this initial experimental cable was constructed and was not employed only because of existing time limitations. Space does not permit a discussion of the pertinent dissection data except to state that the field examination, the observed load and temperature conditions supplemented by laboratory examination and tests on samples adjacent to the fault disclosed conditions that fully substantiate the ascribed cause of failure.

In the case of the type *D* experimental cable, the irregularities in taping associated with the experimental use of 1.5 mil tape in the inner portion of the insulation referred to in the paper and which Sutton has erroneously interpreted to mean "faulty registration" were actually an accidental longitudinal foldover in the innermost 1.5 mil tape, and longitudinal wrinkling, extending through all 1.5 mil tapes. Both failures on the type *D* insulation were related to the thinness of the tapes used and to the very low mechanical tension required in their application as well as to the effect of the relative thinness of the wall as a whole.

The commercial cable type *G*, was designed to be entirely free of ionization up to about twice operating voltage. In the absence of ionization, the cable should operate indefinitely and there should be no need for a higher factor of safety. Examination of a length of the commercial cable removed after approximately five years of operation revealed no significant change in the degree of impregnation, the appearance of the insulation, the dielectric strength or the power factor-temperature characteristic.

In conclusion, the various tests conducted by the authors indicate that the following thermal resistivities may be used as a fair working basis for design calculations:

Paper insulation	550	°C/W/CM³
Pressure medium (Surface resistivity from cable surface to inner wall of the pipe)		
Gas	500	°C/W/CM³
700-second oil at 100° Fahrenheit	400	°C/W/CM³
Pipe coating *A*	100	°C/W/CM³
Pipe coating *D*	71.5	°C/W/CM³
Clay soil	70	°C/W/CM³
Sandy soil	85	°C/W/CM³

Magnetic Recording Tapes

MARVIN CAMRAS
MEMBER AIEE

Synopsis: Paper or plastic tapes with a magnetic coating, as well as solid metal ribbons, have a wide field of use in magnetic recording. Magnetic properties, frequency response, signal-to-noise ratio, output level, sensitivity, and erasability of a number of different tapes are compared. A newly developed coated material has a balance of these properties which makes it especially suitable for high quality magnetic recording.

THE MOST COMMON magnetic-recording tape is a paper or plastic ribbon with a thin layer of permanent magnet material on its surface. Paper tape is economical, gives good performance at low speed, and is easy to handle. It is not as durable as wire and is considerably bulkier, but for many applications these qualities are not important. As with other magnetic record media, the tape can be erased and reused. Figure 1 gives the dimensions of some typical recording tapes and wires for comparison.

In comparing different recording tapes, the ultimate test is the performance in actual use. For speech or music reproduction the performance will depend on frequency response, background noise, distortion, and so forth. But these performance factors are influenced not only by the record medium, but also by the erase, record, and pickup heads; by the kind and amount of bias; by the amplification and equalization; by the tape speed; by the cross section of the magnetic material; and by many other factors. To evaluate the quality of the tape material independently of these influences, it is useful to study such things as magnetic properties, which can be correlated to the performance factors.

Paper 48-75, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 17, 1947; made available for printing December 17, 1947.

MARVIN CAMRAS is physicist with Armour Research Foundation, Illinois Institute of Technology, Chicago, Ill.

Magnetic Properties of Metal Tapes

Steel tapes were used in the early days of magnetic recording. Figure 2 shows the hysteresis loop of a cold-rolled steel tape. All of the oscillograms were made on a curve tracer as described elsewhere.[1] The high residual induction ($B_r = 10{,}800$) gives high output, especially at low frequencies; but the low intrinsic coercive force ($H_{ci} = 10$) indicates poor high frequency response, unless excessive tape speeds are used. Heat-treated steel has somewhat better magnetic properties as indicated by Figure 3. Chrome steel and tungsten steel were also used, but the improvement over carbon steel is relatively slight. While other permanent magnet materials such as "Alnico" have excellent magnetic properties, they are too hard and brittle to be made in tape form. An important advance was the development of "Vicalloy" which had an intrinsic coercive force of 260 and a residual induction of 7,800 as shown by Figure 4.[2] "Vicalloy" tape at present is too expensive for widespread use in such applications as home recorders.

A metallic tape of much lower cost can be made from a stainless-steel alloy similar to that used for round recording wire. Stainless-steel tapes can be run on machines designed for coated tapes. Hence, they can be used for important recordings which should be more permanent than paper-tape records. The durability and corrosion resistance of stainless tape also makes it attractive for advertising devices, announcing systems, and other applications where the material is continually reused, and where weaker material would wear out. Magnetic properties of a typical stainless tape are shown in Figure 5.

The magnetic properties of various metal tapes are summarized in Table 1.

Magnetic Properties of Coated Tapes

One of the first materials tried for coated-magnetic tapes was carbonyl iron which was used on early German tape machines. Carbonyl iron is a fairly soft magnetic material, as shown by Figure 6, with an H_{ci} of 5 and a B_r of 100. As might be expected it makes a poor record medium, both in output and in frequency response.

It was later found that magnetite powder gave improved results, and tapes coated with this material were used on German machines manufactured in the late 1930s. The H_{ci} of magnetite runs as high as 100 to 150, and is responsible for the better performance. Magnetic properties of magnetite-coated tape, of American manufacture, are given in Figure 7.

Figure 1. Cross section of some magnetic recording media

Figure 2. Hysteresis loop of cold rolled steel tape

Figure 3. Hysteresis loop of heat treated carbon steel tape

The highest quality German tapes, which were developed during the war, were made with gamma iron oxide, and a vinyl chloride base material. In one form the magnetic particles were dispersed throughout the carrier to give a homogeneous tape. In the other form, the magnetic layer was deposited on one surface of the tape. Only a limited amount of magnetic matter can be incorporated into the homogeneous tape without serious loss in tensile strength. The homogeneous tape, therefore, has lower B_r than the coated tape. The lower B_r is counteracted to some extent by the thicker layer of active material. Magnetically the gamma iron oxide has properties similar to magnetite, as can be seen from the hysteresis loop of Figure 8.

An experimental tape was coated with vectolite material, made from 30 per cent Fe_2O_3, 44 per cent Fe_3O_4, and 26 per cent CO_2O_3. This is a high grade permanent magnet material with H_{ci} of 880 oersteds, and a B_r of 570 gauss, as shown by Figure 9. (This coercive force was found to be too high. It makes the tape difficult to record, and almost impossible to erase.)

The best all-around coating was one developed at Armour Research Foundation and designated as *140A* material. It has a B_r of 800, and H_{ci} of 340; and is essentially saturated at an applied field of 1,000, which makes it easy to erase. Magnetic properties of the *140A* material are given in Figure 10.

A summary of the properties of coated tapes is given in Table II.

Table I. Magnetic Properties of Metal Recording Tapes

Material	Coercive Force, Oersteds	Residual Induction, Gauss
Carbon steel (cold worked)	10	10,800
Carbon steel (heat treated)	30	10,100
Chrome steel	52	7,000
Vicalloy	260	7,800
Stainless alloy	245	1,725

Table II. Magnetic Properties of Coated Recording Tapes

Material	Coercive Force, Oersteds	Residual Induction, Gauss
Carbonyl iron	5	100
Magnetite	120	375
Gamma iron oxide	110	300
Vectolite	880	570
Armour *140A* material	340	800

Performance Characteristics of Tapes

Probably the most important performance characteristics of tapes are

1. Frequency response characteristic.
2. Maximum signal-to-noise ratio.
3. Output level.
4. Sensitivity.
5. Erasability.

These will be considered separately.

Frequency Response Characteristic

The frequency response characteristic determines the fidelity at a given speed.

Figure 4. Hysteresis loop of Vicalloy tape

A typical constant current response curve for tape is shown in Figure 11. Since it is ordinarily not advisable to equalize the high frequency response more than about 15 decibels, we would say that the tape of Figure 11 could be made to give a flat response to about 8,400 cycles by proper equalization. If this response is better than needed, then the tape speed could be reduced until the required response was obtained. It is seen that an improvement in high frequency response of a tape may result in considerable economy if it allows the tape speed to be reduced.

To illustrate this point a response curve for *140A* tape is shown in Figure 12. With 15 decibels of equalization the response could be made flat to 10,000 cycles. Compared to the tape of Figure 11, the *140A* material could be run 84 per cent as fast for the same response. However, it should be noted that frequency response, though important, is not the only consideration, and other characteristics may determine the final worth of a recording tape.

Figure 5. Hysteresis loop of stainless alloy tape

Signal-to-Noise Ratio

Signal-to-noise ratio determines the dynamic range of the record medium and the amount of background noise on speech or music reproduction. The type of noise and noise-frequency distribution provides an important limitation on the amount of equalization, so that indirectly the signal-to-noise ratio may affect the frequency response. One advantage of magnetic recording is the low background noise.

For a true measure of signal-to-noise ratio, the tape should be operated in circuits which have the same equalization and band width as those used in ultimate operation. Since conditions of ultimate operation will vary according to use, a signal-to-noise figure should be accompanied by a description of the conditions under which it was taken. For purposes of comparing the various media, the signal-to-noise ratio was determined under conditions of constant recording current, and playback through an amplifier flat from 20 cycles to at least 20 kilocycles. Recording and playback speed was one foot per second, and the tape channel width was 0.125 inch. The maximum signal level was taken as the output decibels for saturation recording intensity at the frequency of maximum response. The noise level was taken as the output of an erased tape under the same conditions.

Figure 6. Hysteresis loop of carbonyl iron coated tape

Figure 7. Hysteresis loop of magnetite coated tape

Figure 9. Hysteresis loop of Vectolite coated tape

Figure 8. Hysteresis loop of gamma iron oxide coated tape

Figure 10. Hysteresis loop of *140A* coated tape

Tables III and IV compare the signal-to-noise ratios of various tapes tested. It should be noted that in some cases the noise level is so low that it is partially masked by vacuum tube noise of the preamplifier. In these cases, the signal-to-noise ratio is specified as at least that number of decibels.

In addition to the "erased noise" heretofore described, there is also a noise which varies with the recorded signal, and has been termed "modulation noise."[3] If this noise is kept below a certain level, it is marked by the signal, and is not considered troublesome.

Output Level

A high output level from a recording tape is desirable for several reasons. Less amplification is needed, and in some cases an amplifier stage may be omitted. A narrower track can be used, allowing economy of material. Hum level and tube noise are reduced at the lower amplification, thus improving the over-all signal-to-noise ratio.

For comparison among various tapes the maximum signal output level at frequency of maximum response is tabulated in the third column of Tables III and IV. The output voltage in all cases was determined for a 0.125 inch wide track and tape speed of one foot per second, with adjustments made so as to give the best performance for each tape.

The metallic tapes have high outputs, mainly because the active material is thicker than on coated tapes. On the other hand, the maximum output of coated tapes occurs at a higher frequency, and at high frequencies the voltage from the coated tape may exceed that from the solid metal tape.

Sensitivity

Sensitivity is defined by the equation

$$S = K \frac{V_0}{I_1}$$

where

S = sensitivity
V_0 = output voltage on playback
I_1 = recording current
K = a constant depending on test apparatus and conditions

A typical curve of output voltage versus input current is shown in Figure 13. Since this function is practically linear below overload levels, the sensitivity of a given tape is substantially constant. In general, the sensitivity will vary with the frequency and with the bias adjustment. For comparison purposes the frequency and bias were adjusted to give maximum sensitivity on each of a number of tapes. The results are tabulated in column four of Tables III and IV.

The metallic tapes are generally more sensitive than the coated tapes because of their greater output. Of the coated tapes, it would be expected that low coercive materials would be most sensitive. The *140A* material turns out to be more sensitive than the others; though its coercive force is relatively high, the B_r rises rapidly after a critical value of field is reached.

Erasability

One of the important advantages of magnetic recording is that the record may be erased if desired, and a new record made in its place. To insure that a magnetic record will be erased completely, it must be subjected to a field high enough to produce magnetic saturation. This is readily done if a permanent magnet or a d-c field is used. However, a tape erased with direct current is likely to be noisy; also it will have even order distortion if a subsequent attempt is made to record by the supersonic bias method.

Figure 11 (Left). Constant current response of stainless alloy recording tape

Figure 12 (Right). Constant current response of *140A* recording tape

Figure 13. Linearity of output voltage versus input current at low levels

Figure 14 (left). Experimental magnetic-tape recorder

Figure 15. Over-all response of experimental recorder

For best results the tape is demagnetized by an a-c erase magnet. The ease with which a material erases depends not only on its coercive force, but also on how easily it saturates. Some materials reach most of their B_r at a low field, but saturate slowly, the B_r continuing to rise even for fields of several thousand. These materials are difficult to erase. Others saturate at low fields even though they have relatively high coercive force.

In general, materials with a coercive force below 200 are easily demagnetized. Those with a coercive force of 350 to 400 are intermediate. Tapes with coercive forces above 400 are difficult to erase.

Erase heads which operate satisfactorily with standard materials require so much input to clean the high coercivity tapes that they may overheat, causing melting of the tape coating and other troubles. The relative ease with which different materials may be erased is given in column 5 of Tables III and IV.

Table III. Performance Characteristics of Metal Recording Tapes

Material	Thickness, Mils	Max. Signal to Noise Ratio, Db	Max. Output Level, Volts	Relative Sensitivity	Relative Erase Power
Carbon steel (cold worked)	1.0	44	0.050	6.1	0.025
Vicalloy	2.0	62	0.120	5.2	0.090
Stainless alloy	1.0	62	0.075	1.2	0.160

Table IV. Performance Characteristics of Coated Recording Tapes

Material	Thickness, Mils	Max. Signal to Noise Ratio, Db	Max. Output Level, Volts	Relative Sensitivity	Relative Erase Power
Carbonyl iron	1.2	34	0.001	0.016	0.250
Magnetite	0.5	58	0.020	0.390	0.130
Gamma iron oxide	0.6	64	0.036	1.400	0.032
Vectolite	0.8	60	0.090	0.810	2.000
Armour *140A* material	0.5	68	0.120	5.300	0.190

Experimental Recorder

Figure 14 shows an experimental recorder designed to take advantage of the properties of the *140A* tape material. The tape is stored on an 8-millimeter movie reel, which will hold programs up to an hour in length. Two channels are used on the one-fourth inch wide tape. When the tape passes from the right-hand to the left-hand spool, the upper channel plays. When it drives in the opposite direction, the lower channel is in the circuit. Thus, no rewinding is necessary, and a program is always available.

Over-all frequency response of the system is shown in Figure 15. At eight inches per second the output is flat within ±3 decibels from 50 to 7,000 cycles. This system is capable of response to 10,000 cycles at the same speed if desired. The signal-to-noise ratio is better than 45-decibels, and at normal recording levels the total harmonic distortion is approximately 1.0 per cent.

Conclusions

A large number of physical and magnetic properties must be considered in evaluating the suitability of a material for a magnetic recording tape. Solid metal tape is best for durability and repetead use. Coated paper or plastic tape is not as permanent, but is lighter, easier to handle, and less expensive.

The best coating material for tapes has high coercivity and retentivity. It should saturate at relatively low fields for good erasing.

A Turn-In-Gap Erase Head for Magnetic Recorders Providing Intense High-Frequency Fields

D. E. WIEGAND
MEMBER AIEE

R. E. ZENNER
NONMEMBER AIEE

Synopsis: A new erase head structure has been devised for use in magnetic recording. This new head provides, at reasonable power inputs, much more intense erasing fields than were possible previously and thus makes the use of magnetically harder media feasible. This head is excited by a single conductor in the erasing gap. The gap conductor is energized by a single turn secondary winding of a transformer. Greater efficiency is achieved through the resulting reduction in head flux for a given magnetomotive force applied to the medium. Also, improved thermal characteristics increase the power handling ability of this head.

IN A MAGNETIC recorder, remanents of previously recorded signals not completely erased contribute to the background noise level of a new recording. Particularly in a high quality recorder, it is desirable to keep the background-noise level as low as possible. In typical low cost home recorders stray hum pickup, amplifier microphonics, and similar disturbances rather than wire noise are controlling factors in the over-all background noise of the machine. With presently used magnetic recorder media a degree of erase entirely satisfactory under these conditions is obtained easily with conventional head structures. In a high quality machine, however, these other disturbances are reduced sufficiently that essentially only the wire noise remains. To realize the benefits of this low random background noise level requires that the erase head be able to completely erase previously recorded signals. With the tendency toward media of higher and higher coercivity this has often been quite a difficult problem with conventional erase head structures. Head heating and relatively high oscillator power requirements have been serious problems in some cases. The problem would be much less severe if the old d-c erase d-c bias (Poulsen) system[1] were used. The modern a-c erase a-c bias system[2] is greatly to be desired, however, because of its greater dynamic range and lower distortion.

The improved frequency response characteristics possible with a medium having high coercivity[3] explains the tendency toward these magnetically harder materials. The turn-in-gap erase head design provides high-frequency fields of sufficient intensity to completely erase such media. Moreover, the improved efficiency of this design make the oscillator requirements less severe.

The Turn-In-Gap Erase Head Design

The usual high-frequency erase head consists of one or more laminations forming a magnetic circuit which is closed except for a narrow gap. An exciting winding is wound around part of this magnetic circuit. The recording medium travels over a portion of the magnetic circuit including the gap. When the coil is excited by a high-frequency current, a magnetomotive force is developed across the gap and, therefore, across the length of medium over the gap. The gap is so proportioned that an element of medium is subjected to several reversals of the high-frequency flux while it is over the gap, and so that the field strength dies out gradually on both sides of the gap. Erasing action, therefore, is similar to the commonly used method of demagnetizing a ferromagnetic object with an a-c field. Since the permeability of the recording medium under erasing conditions is very low, 3 or less, it is evident that only a small portion of the flux in the core gets into the medium.

The magnetic flux in the head core is equal to the sum of the flux in the medium plus various stray (nonuseful) fluxes. In a typical erase head, the power input is determined mainly by hysteresis and eddy losses in the head core. Copper losses in the exciting winding usually are much smaller. It is evident, therefore, that if the nonuseful fluxes for a given gap magnetomotive force are reduced, a significant gain in erase head efficiency will result, through the reduction in operating flux density in the head core. In electromagnetic apparatus in general, nonuseful fluxes are minimized by placing the excitation of the system as near as possible the region where the magnetomotive force is desired. This region in an erase head is directly above the gap in the core.

The turn-in-gap erase head is excited by a thin copper strap in the gap directly below the recording medium. From the discussion above it is evident that, for a given magnetomotive force across the gap tips, the flux in the head core is significantly less than in structures which are excited by windings around one or more legs of the core. A further gain in efficiency results from the reduced mean length of flux path. The minimum path length is around the gap strap on the turn-in-gap head, rather than around the core window in a conventional head.

Efficient excitation of the head with an electronic oscillator requires the use of an impedance matching transformer. To

Figure 1 (left). Construction of turn-in-gap erase head

Figure 2. Turn-in-gap, combination, and solder-lug heads

minimize losses in the secondary circuit, the transformer and head are built as an integral unit in such a way that the length of the secondary circuit is a minimum. The unit is proportioned so that transformer losses and those in the secondary leads are small compared to the losses in the head itself.

Most of the development work on the turn-in-gap erase head has been on a design for use with round wire media and it is this design that will be described. The same principles were used in an erase head for magnetic tapes and were found to give good results in this case also.

The general construction of the turn-in-gap erase head is shown in Figure 1. The assembly of head laminations and gap strap shown at the top of Figure 1 is slid down between the facing surfaces of the secondary turn, the gap strap being fitted into the slots in the ends of the secondary turn. The secondary turn is then clamped over the surfaces immediately below the gap strap, after which the gap strap is soldered to the secondary turn around the edges of the slots. Finally, the bottom of the wire groove is rounded, and the ends of the groove are beveled and rounded for knot passing action.

The size of the turn-in-gap head relative to that of two other types is evident from Figure 2. Head *b* is a combination erase, record, and play-back head, *c* is an erase head in which improved efficiency was obtained by reducing the mean length of the magnetic path. This was done by reducing all dimensions to practical minima.

Erasing efficiencies of these heads were obtained by recording a signal at saturation level on a length of wire. By passing this wire over the erase head under study and measuring the remanent signal corresponding to varying currents in the erase head, data relating remanent signal level with erase current were obtained. A special play-back system described in the next section was used in these tests. The effective a-c resistance and inductance of each of the heads were measured with a Maxwell bridge.[4] This bridge was arranged to allow these measurements to be made under operating conditions of current and frequency, about 40 kc per second. Values of power input to the heads were calculated from the effective resistance values and values of current in the erase tests. In the case of the turn-in-gap head, the impedance measurement was made at the terminals of the primary winding. Losses in this winding and in the transformer core were thus included.

Characteristic of the Measuring System

In a high quality magnetic recording system remanent signals at the approximate level of the background wire noise will be audible and, therefore, objectionable. Measurement of remanent signals at this and lower levels requires the use of a tuned play-back system. Measurement of low level signals usually is made difficult by the interfering effect of noise generated in the first stage of the play-back amplifier. In the play-back system used in these tests this problem is made much less severe through the use of a play-back head–transformer combination providing a much higher signal to the amplifier input than usually is obtained. This was done by selecting a step-up ratio in the input transformer which gave the maximum peak signal on a series of frequency response curves, each for a different step-up ratio. This system has greater losses at high frequencies than would be tolerable in a sound recorder but the characteristics are suitable for the erase head study, since it is found that, in general, high-audio frequencies are more easily erased than medium or low frequencies.

The play-back system is shown schematically in Figure 3. Either broad band or tuned measurements can be made with this system. For broad band measurements, readings are obtained directly from the vacuum tube voltmeter. The vacuum tube voltmeter is provided with output terminals which allow its use as a calibrated amplifier. For tuned measurements these output terminals are connected to the input of a sound analyzer through a matching resistor. The sound analyzer is a frequency selective amplifier operating on the constant percentage band width principle. That is, the width of its resonance curve in cycles per second is proportional to the frequency setting of the tuning dial. The play-back system is calibrated to measure the voltage at the input of the 100/1 amplifier.

The characteristics of the play-back system are shown in Figure 4. The wide band play-back curve was obtained by measuring play-back voltages of a variable frequency recording which had been recorded with a constant current such that the play-back level was about nine decibels below saturation level. As mentioned previously, the loss at high frequencies is greater than would be tolerated in a sound recording system. The advantages of this high level system for measurements of this type are evident from a comparison of the saturated signal level, 81 decibels with the system noise level, five decibels. System noise includes all distrubances except that of the wire noise, such as hum pickup,

random noise and microphonics in the amplifiers. With this same wire in a high quality sound recording system it would be difficult to hold the system noise to a level 65 decibels below the saturation level. A further gain in measuring range is possible through the use of the tuned play-back system. In this case, the system noise is about 100 decibels below the saturation level. This is equivalent to a measuring range of 100,000 to 1 on a voltage basis or 10^{10} to 1 on an energy basis. This range is more than sufficient for the erase head measurements.

Recordings at 700 cycles per second were used in obtaining data for the erase head characteristics. This frequency is high enough so that, with the play-back system tuned to this frequency, the interfering effects of stray fields at the power line frequency and its harmonics are negligible. This frequency is low enough so that measurements can be made at the second and third harmonics of the recorded frequency—1,400 cycles per second and 2,100 cycles per second. It was thought to be possible an erase head might erase the fundamental component of the recorded signal but leave harmonic components on the medium. This was found not to be the case, however. No second harmonic could be detected under any condition of measurement. A third harmonic component in the remanent signal was measurable, particularly at low values of erase current where the remanent signal was only slightly below the saturation level. The measurements indicated, however, that the major portion of energy in a remanent signal is at the recorded frequency and that measurements with the play-back system tuned to the recorded frequency are a sufficiently accurate measure of the total energy left in the medium.

Performance of Erase Heads

Data for the curves of Figure 5 were obtained by using apparatus and test methods described in the previous section. The recordings were made at 700 cycles per second and at saturation level. The play-back system was tuned to this frequency in making the remanent signal measurements. The magnetic properties of the recording wire used in these tests are typical of presently used wires. A loop of wire driven at two feet per second was used.

The heads used in these tests were handmade. Magnetic parts were made by cutting them from annealed sheet stock with a fine saw. The pieces were not annealed after cutting. While care was taken not to bend the magnetic material, it is known that even the cold working due to sawing has an adverse effect on the magnetic properties. Performance of each of the erase head types, therefore, would be somewhat better than that shown in Figure 5 if the magnetic parts were annealed after fabrication.

After the maximum erase with the turn-in-gap head, the sound analyzer was detuned slightly in both directions from the frequency of the recorded signal. No change in level was detected. This indicated that the recorded signal had been completely erased and all that remained on the wire was random noise.

Erasing action sufficient to reduce a saturated signal 40 decibels probably is satisfactory in a low-cost home recorder because (*a*) in such a recorder hum and amplifier disturbances rather than wire noise determine the background noise level which, because of economic considerations, probably will be no more than 40 decibels below the saturated signal level; (*b*) a recording made at proper level should be saturated upon signal peaks only, if at all, and signal levels below the saturation level are more easily erased than saturated signals; (*c*) remanent signals can be further reduced by running the wire through the erase head several times. It is evident from Figure 5 that the turn-in-gap head provides this degree of erase at about 0.6 of the power required by the solder-lug head and 0.4 of that required by the combination head. These lowered power requirements probably are sufficient to allow the use of a smaller oscillator tube with corresponding savings in the power supply.

Through refinements in design in a high quality recorder, the over-all background noise level of the machine, including wire noise, may be reduced to a level 60 or more decibels below the saturated signal level. In order that they do not contribute significantly to the over-all background, remanent signals should not exceed a level 70 decibels below the saturation level in such a machine. This degree of erase 10 decibels in Figure 5 is obtained with a power of 2.6 watts in the turn-in-gap head. Neither the combination head nor the solder-lug head of Figure 2 will operate continuously at this degree of erase without overheating. In fact, in obtaining data for these heads at high current it was necessary to limit the time of application of the current. This precaution was not necessary with the turn-in-gap head. While temperature runs have not been made on these heads, the 2.6 watt input to the turn-in-gap head definitely is a safe value. This head has been operated at approximately four watts for a long period of time with no signs of damage due to overheating.

A turn-in-gap erase head has been in use in a tester for routine tests on wire samples at the Armour Research Foundation. A wide variety of wires, some considerably more difficult to erase than presently used wires, have been tested. It has been possible in all cases to completely erase saturated signals on these wires. In this tester, the condition of complete erase is determined by a listening test. The high frequency current in the erase head is increased until the remanent signal is completely masked by the random background noise.

With previous erase head designs it has been extremely difficult to restore to a wire a background noise level as low as the

Figure 4 (right). Characteristics of play-back system

Figure 3 (below). Play-back system for erase head tests

Figure 5. Performance of erase heads

level prior to the recording of any signals. With the turn-in-gap head it is possible to reduce the noise level of a virgin wire (as-drawn) by about four decibels. This lowered noise level also could be obtained after recording a saturated signal and erasing this signal. These noise measurements were made under the conditions of restricted high frequency response in the special test setup (wide band play-back curve of Figure 4). It was found that effective erasing action with this new type head does not require good magnetic contact between the wire and head groove. As the wire was gradually lifted out of the groove, no decrease in erasing action was noted until the wire reached the top of the groove.

There are two basic reasons for the improved efficiency and greater available erase power in the turn-in-gap head.

1. Major losses in an erase head are those in the ferromagnetic structure. For a given erasing field these losses are reduced in the turn-in-gap design by reduction of the head flux for a given erasing field through reduced stray fluxes, and by reduction in effective length of flux path—the minimum length flux path is the shortest distance around the gap strap rather than around the window in a conventional head.

2. Use of a constricted part, gap strap, of very short length in the secondary turn, and provision of good thermal contact between the gap strap, the head laminations, and the major part of the secondary turn allows the rapid removal of heat from regions of high loss concentration—gap strap and head laminations. These improved thermal characteristics allow the head to be excited to higher flux densities than is usually possible without excessive temperature rise.

Conclusion

The turn-in-gap erase head is more efficient than other types in that less power is required for a given effectiveness of erase.

Improved heat dissipating characteristics of the turn-in-gap head together with its improved efficiency, allow this head to supply erasing fields of sufficient strength to obliterate completely all effects of previously recorded signals on any wires that are likely to be used in magnetic recorders.

With the turn-in-gap erase head, broad band wire noise, as measured with the equipment described, can be reduced to a level lower than that of the virgin wire noise level measured under the same conditions.

Western Union Teletape Facsimile

LEON G. POLLARD
NONMEMBER AIEE

IN THE APPLICATION of facsimile to the telegraph industry, development has primarily been directed toward the adaptation of such equipment to the handling of regular telegraphic traffic in the form of messages on telegraph blanks. The introduction of Western Union's "Teledeltos" recording paper some years ago provided a practical recording medium which was one of the principle things necessary to make facsimile telegraphy a success. Facsimile messages can be recorded directly on teledeltos paper made up in the form of telegraph blanks, and without any special processing or handling, these messages are ready for delivery.

A number of articles[1-4] have been published describing the equipment which has been developed by Western Union engineers and is now used on Western Union railroad and airline facsimile telegraph circuits. Some machines require the message to be manually placed in position on the drums while other machines are self-operating to the extent that it is only necessary to drop a message in a slot of the transmitter and it is automatically wrapped around a revolving drum, scanned and transmitted to the receiving instrument, where the functions of loading, recording and discharge of the message are again automatically performed.

In all machines of this class the light-beam scanning and photoelectric method of pickup is used and recording is accomplished by means of a metallic needle point on teledeltos paper. During the war civilian engineers at Camp Coles Signal Corps Laboratory made the discovery that pencil marks on teledeltos paper provided a convenient medium for conductive pickup. While optical methods of pickup in general produce excellent copy and do not require special papers, the cost of the necessary components somewhat restricts the field of application. With the disclosure that teledeltos paper can be utilized for the purpose of transmitting as well as receiving facsimile messages, an entirely new field for this system of communication has become available. It has been realized that there is a need for a simple means of transmitting written intelligence between one or more points such as are now served by oral or other local intercommunication systems. There are many instances where a recorded rather than an oral message is necessary or desirable, and there are many cases where it would be convenient to communicate to periodically unattended points where the messages would be on record for future handling.

With such possibilities in mind, Western Union has developed facsimile equipment to fulfill these requirements. The machine used for this purpose is a transceiver which is called the "Teletape." It has been so named because teledeltos paper in the form of tape provides a convenient and practical way of accomplishing the dual purpose of transmitting and receiving. These teletape transceivers, which are of small dimensions, are located at the terminals of a 2-wire circuit, and will operate satisfactorily when these terminals are separated by a distance up to several miles. Messages written directly on teledeltos tape are scanned, transmitted over the line and reproduced in facsimile form on the tape at the opposite end. Transmission can be carried out in either direction as the machines automatically function as transmitters or receivers.

Figure 1. Principle of the teletape scanning system

As this is the first time that teledeltos paper has been used in this capacity, several problems encountered in the development of this system may be of interest. When using teledeltos for transmitting purposes, the intelligence is impressed on the surface of the paper either by means of a soft lead pencil or from a specially prepared carbon paper. In the teletape system a pencil is used. As the message is written, the film on the surface of the paper is ruptured and graphite from the pencil forms a low resistance path through the paper. The paper which has a conductive backing is supported by a metallic platen and scanning is accomplished by means of a fine metal stylus which is progressed across the surface. As the point of the stylus passes over the paper, the resistance between the stylus and the platen is reduced by several thousand ohms at the points where the film of the paper has been broken and graphite deposited. This resistance change is utilized as the actuating impulse in this method of pickup. For satisfactory operation of this conductive pickup system it is necessary to use a stylus having a small area of contact and yet of such design that the surface film of the paper will not be damaged during scanning.

After the investigation and trial of a number of standard scanning systems, a simplified method has been developed for the teletape in which several of the difficulties encountered in other systems have been overcome. In all facsimile systems there are two fundamental requirements which must be fulfilled. First, the facsimile receiver must run in synchronism with the transmitter, and second, some method must be employed

Paper 48-74, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 12, 1947; made available for printing December 19, 1947.

LEON G. POLLARD is assistant electronics research engineer with Western Union Telegraph Company, Watermill, N. Y.

Figure 2. Simple model for the rotary scanning of narrow tape

Figure 3. Exploded view of teletape scanning head

for phasing the machines to insure proper registration of the received message. When both ends of the circuit are powered from the same 60-cycle system, synchronism is automatically maintained. However, phasing is still required and is usually accomplished by means of a phasing pulse from one end of the circuit, which through a system of relays and commutators, orients the machine at the opposite end.

Figure 1 illustrates the principle of the teletape scanning system. Teledeltos tape having a width of 3/4-inch is directed through a concave guide and passes by a rotating four-pointed stylus which brushes over the surface of the paper. This stylus is mounted on the shaft of a small synchronous motor running at 1,800 rpm. The concave guide has a radius of exactly 1/2-inch about the axis of the stylus shaft and the diameter across the tips of the stylus is slightly in excess of one inch. A narrow recess is machined in the concave guide directly behind the line of contact of the stylus with the tape. The radius of the stylus being somewhat greater than that of the concave guide results in the tape being slightly depressed into this recess as it passes by the stylus during scanning. This insures a positive rubbing contact of the stylus tips with the surface of the tape. Furthermore, as the tape passes over the recess in the guide, the edges are flattened just sufficiently to allow the tips of the stylus to miss contact at the extreme edge and prevent cutting the paper.

Figure 2 shows a simple model which was constructed to determine the possibilities of this system of scanning and recording. The same stylus is used for conductively picking up a message which has been written on the tape or for electrically recording a message fed to it from another similar machine.

It will be observed that with a 4-pointed stylus, one point for each pole of the 1,800 rpm motor, phasing of the transmitter and receiver each time they are started is no longer necessary. Initially, it is necessary that the multiple pointed stylus on each machine be so adjusted that the tips are in the same relative position with respect to the motor poles, but thereafter, providing of course that both the transmitter and receiver are powered from the same 60-cycle system, no phasing is required. Initial phasing is easily accomplished by marking a straight line at a definite position on the tape and transmitting this sample to the receiver. The receiver is then adjusted to bring the recorded line to the same position. It will also be observed that the 90-degree displacement of the stylus tips on a slightly greater than 1-inch diameter is in excess of the width of the tape by just a sufficient amount to prevent simultaneous contact of two tips with the tape. This results in approximately 95 per cent of the line time being utilized for message transmission.

Figure 3 shows an exploded view of the scanning head used in the teletape machine. A polished cylindrical housing serves as a platen against which the tape is firmly pressed by a concave shoe as it is drawn through the machine. The stylus is a thin 4-pointed metal wafer so constructed that the tips are accurately spaced by 90 degrees and of equal radius. The narrow recess in the concave shoe aligns with a cutout portion of the cylindrical housing and the stylus engages the tape at the center of this opening. The cylindrical housing also contains two precision type ball bearings supporting the rotating stylus shaft. On one end of this shaft is a small miter gear, which when assembled in the machine, engages a similar gear mounted directly on the shaft of the synchronous motor. The other end of this shaft carries an insulated stylus mounting provided with a knurled thumbscrew to hold the stylus rigidly at right angles to the shaft. On the surface of this stylus mounting is a small pin which engages a hole punched in the stylus. This orients each replaced stylus in a definite relationship with respect to the motor poles, which as mentioned before, is the only requirement necessary to take care of the phasing problem.

Figure 4 shows a type *5006-A* transceiver and its associated power and con-

Figure 4. Transceiver 5006-A with power control unit 5046-A

Figure 5. Teletape transceiver with tape-guide cover partly opened

Figure 7. Inside view of transceiver showing tape pull-off mechanism and stop switch

trol unit type *5046-A*. These two units connected together through a 12-conductor flexible cable comprise one terminal of a teletape circuit. The transceiver unit consists of the scanning mechanism, a tape reel holding a $5^1/_2$ inch roll of teledeltos tape, and a pull motor for feeding the tape through the machine. The power and control unit contains the transmitting and receiving amplifiers and the necessary relays and power supply equipment. When installed in an office or other terminal position, the transceiver unit is placed in a convenient location for the user and the power control unit is located in a more or less out of the way place where it is accessible only for turning on and off once a day.

Figure 5 shows the transceiver only. It will be noticed that in the top of the machine is a long narrow opening. In this opening and flush with the top of the case is a writing platform over which the teledeltos tape from the storage reel is passed. A hinged cover with a short projecting handle covers this tape guide. In this particular model of the teletape the opening and closing of this cover actuates switches which in turn operate the circuit control relays. When not in use the covers should always be left in a closed position to maintain a normal stand-by condition. To illustrate the operation of the machines, let us assume that station *A* desires to transmit a message to station *B*. The operator at station *A* first opens the cover over the tape guide. This is necessary to expose the tape on which the message is to be written, but as the cover is opened, a circuit is made which lights indicating lamps at both stations *A* and *B*. At the same time cover locks at both stations are energized and the cover over the tape guide at station *B* is now locked in a closed position until the completion of the transmission. This prevents the operator at station *B* from attempting a simultaneous transmission. The operation of opening the cover at station *A* also energizes relays at both ends of the circuit so that station *A* will function as a transmitter and station *B* as a receiver for this particular transmission. After the operator at station *A* has written his message on the tape, he closes the cover. This operation of closing the cover starts the motors and scanning mechanisms at both terminals and transmission is accomplished. At the end of the message both machines are automatically stopped and restored to a stand-by condition ready for the initiation of another transmission from either end. When the cover at station *A* was closed it also was latched to prevent further opening until this message had been completed.

Should station *B* desire to transmit to station *A*, the same functions are carried out in a reverse direction. Opening the cover at either end of the circuit preempts the circuit for transmission from that end and at the same time prevents the operator at the opposite end from attempting to initiate a transmission.

Figure 6 is a view of the interior of the machine. It shows the relationship of the scanning head, tape reel and writing platform and the tape pulling gear with its associated motor. The scanning head motor located behind the supporting bracket drives the scanner through a miter gear. It is mounted on a circular plate capable of rotation about the center of the motor shaft by which means the relationship of the motor to the stylus may be conveniently changed for initial phasing purposes. It will be observed that as the tape leaves the writing guide it passes over a roller and then assumes the concave form in passing through the scanning head. It thence passes over a second roller and through the draw-off mechanism.

Figure 7 shows the reverse side of the machine. The tape draw-off motor as well as the scanning motor is of the synchronous type. Connected through a reduction mechanism from this motor is a low-speed gear which makes one complete revolution during the transmission of a single message. A lever on this gear wheel actuates a trip switch just as the end of the written message is exposed out of the side of the machine. The motors of both machines are thereby stopped at the same instant at the end of each transmission.

As mentioned before, a-c power to the machines can be turned on at the beginning of the day and turned off at night. This insures that the amplifiers are in a warmed-up condition and ready for instantaneous operation. In order that the operator at one end of the circuit can be

Figure 6. Inside view of transceiver showing scanning mechanism

Figure 8. Block diagram of teletape terminal installation

assured that the equipment at the opposite end is in an operating condition and ready to receive messages, a series line switch is incorporated with the power switch. The initiating circuit which is energized when either cover is opened, is a series circuit through both line switches. If, when the operator at one end lifts the cover on his machine, the signal lamp at his end does not light, he knows that power has not been applied to the distant end and no message can be transmitted.

Figure 8 is a functional diagram showing a teletape terminal installation. In this particular model of the teletape, the length of exposed tape in the tape guide on which a message may be written is 11 inches. The transmission time for each message is 18 seconds. The tape reel holds a 600-foot roll of tape which is sufficient for a total of about 325 messages. Development work is now in progress to determine the most satisfactory material from which to fabricate the wafer type of styli for this machine and also the possible advantages of other forms of multi-pointed styli. The styli used at present are hardened steel and each stylus has a life of between 300 and 400 messages. A worn stylus may be easily replaced.

The teletape terminal electronic equipment consists of two amplifiers, one each for transmitting and recording. The conversion of the written message to electrical impulses is somewhat unique in that the circuit from the stylus through the teledeltos tape to ground forms one arm of a Wheatstone bridge, the output of which is fed to the transmitting amplifier. The signal frequency applied to the bridge is generated by a 5,000-cycle local oscillator. This comparatively high frequency is dictated by the high scanning speed of 94-inches per second employed in this system. If the bridge is balanced for background resistance, positive transmission results, because a pencil mark on the tape unbalances the bridge with consequent signal to amplifier. Conversely, if the bridge is balanced for a solid mark on the tape, negative transmission results. Practice limits line input levels to about zero decibel above one milliwatt and one stage of amplification following the bridge is more than adequate to fulfill this requirement.

The recording amplifier consists of a voltage amplifier triode and a power amplifier pentode which has a high impedance output to the recording stylus. Adequate gain is provided so that this equipment may be operated over lines with as much as 30-decibel loss.

Figure 9 is a view of the interior of the power control unit. On the lower chassis are the signal control relays and the power supply while the upper chassis carries both the transmitting and receiving amplifiers.

Figure 9. Interior view of power control unit

Figure 10. Typical installation of a teletape machine

From this description one may see why the teletape, utilizing facsimile as a means of transmission, is finding applications to intercommunication systems. It provides a means for the speedy transfer of written intelligence from one point to another. It does not require the immediate attention of the recipient and it can be handled by anyone without the need for special training in its operation. There are a great many instances where such a system is desirable. A specific application is the linking of a teller in a branch bank with the bookkeeping department, located in another building. An experimental installation of this type is giving satisfactory service in one of the New York banks. The teller can place a request for certain information via the teletape, proceed with his work and receive an answer with a minimum of attention. Figure 10 illustrates an installation of this type.

Another similar application is the connection between a ticket clerk and the reservation bureau such as found in railroad stations and airline offices. The ticket clerk can ask for a reservation for one customer and continue with succeeding customers while the necessary information is being obtained and recorded. Many other applications such as dispatching systems and quotation services are becoming apparent. At present, teletape equipment is undergoing tests with a view to proceeding with its manufacture and distribution as soon as all the apparent operational requirements have been fulfilled. It is hoped that the teletape with its comparatively simple method of operation will in a small measure contribute to the advancement of the art of facsimile communication.

Survey of Lightning Protective Equipment for Rotating A-C Machines

AIEE LIGHTNING PROTECTIVE DEVICES SUBCOMMITTEE*

THIS SURVEY was initiated to determine the present practices used to protect rotating a-c machines against lightning.

Method Employed

Permission was obtained from the Edison Electric Institute to circularize the members of the Electrical Equipment Committee with a short questionnaire on this subject. This questionnaire is shown as Figure 1.

Coverage of the Industry

The members of the Electrical Equipment Committee are well dispersed throughout the country.

In all, questionnaires covering 61 companies were sent out. From the McGraw Central Station Directory for 1945 the companies solicited that rated their generating capacities in megawatts, produced a total of 12,465 megawatts, and those reporting in megavolt-amperes produced a total of 11,030 megavolt-amperes. If a nameplate rating of 0.9 power factor is assumed for those reporting in megavolt-amperes the sample adds up to 22,390 megawatts, nearly 45 per cent of the installed generating capacity in the country.

Since the information was obtained from the foregoing source, no plants operating under government agencies are included. It happens further that since no members of the group solicited were from the companies operating in New York City and Chicago these two large centers are not included in the results.

Of the 61 companies solicited, replies were received covering 54 of the companies.

Analysis of Questionnaire Replies

Table I shows the specific answers to the questions in detail. However, certain comments can be made with respect to the practices and ideas expressed in the tabulated replies:

1. Of the companies answering, 30 definitely favor protection and have installed it; 16 do not have the equipment installed, except in special cases; 8 companies have had such equipment recommended to them for installation.

2. The minimum size of machine protected varies greatly. In some cases this happens to be determined by the possible exposure, and the minimum size is determined by this, rather than the establishing of a definite size below which protection is not applied This also affects the number of machines protected.

3. Machine failures due to lightning before the protective equipment was installed vary

American Institute of Electrical Engineers Lightning Protective Devices Subcommittee

Survey of Lightning Protective Equipment Used for Rotating A-C Machines

1. Does your company use lightning protective equipment for rotating a-c machines? Yes..... No.....
2. What size of machines is it your practice to protect? .....Kva and larger.
3. How many machines of this kva rating and larger do you have on your system? .....
4. To how many of these machines have you applied lightning protective equipment? .....
5. How many of these machine failures did you have from lightning before lightning protective equipment was applied? .....
6. How many of these machine failures have you experienced from lightning where lightning protective equipment was applied? .....
7. What lightning protective equipment do you use?
   (a) Lightning arresters only? Yes..... No.....
   (b) Capacitors only? Yes..... No.....
   (c) Combination of Arrester & Capacitor? Yes..... No.....
8. Is it your practice to use arresters of reduced rating where the neutral of the machine is solidly grounded ($X_0/X_1 = 3$ or less)? Yes..... No.....
9. Is it your practice to apply lightning protective equipment to machines?
   (a) Directly connected to overhead lines? Yes..... No.....
   (b) Connected through transformers? Yes..... No.....
10. What is the attitude of your company toward application of lightning protective equipment of rotating a-c machines:
   (a) Has it been worth while? Yes..... No.....
   (b) Do you expect to apply more of this equipment in the future? Yes..... No.....
   (c) Give any comments you may have on this subject, particularly your estimate of the average number of thunderstorm days per year on your system.

Table 1. Answers to Questionnaire on Lightning Protection for Rotating A-C Machines (Continued)

Company Reporting	9 (a)	9 (b)	10 (a)	10 (b)	10 (c)	Remarks
1				Yes	70	New installations have been protected, practice not general on system
2	Yes	Some	?	Probably		Tests are in progress to determine proper functioning
3		Yes		Yes		
4	Yes	Some	?	Probably		Tests are in progress to determine proper functioning
5						Special case of 1,000 kw M-G set. New coils installed and no failures since, although protection was installed six months before coils were replaced
6	Yes	Yes	Probably	Yes		Some variation between divisions based upon experience
7	Yes	Yes	Yes	Yes		Practice will be extended as soon as possible
8	Yes		Yes	Yes		Smaller machines (375 to 15, 625 kva) connected to buses with lightning arrester protection on the bus
9	No	No	No	No	60	
10	Yes	No	Yes	Yes	41	
11		Yes		Yes	40	
12	Yes	In some cases	Yes	Yes		
13						Included in company number 30
14	Special cases only		No	Special cases only	40	Present special installations to be removed. Rotating machines generally connected to underground system
15	Yes	Yes	Yes	Yes		60 Machines connected to buses protected by arresters. Arresters and capacitors used in some cases where windings are multiturn coils
16		Yes		Yes		
17	Yes	Yes	Yes	Yes	33	Capacitor and lightning arrester combination used on hydro units to protect old, damp insulation
18	Yes	No	Yes	Yes	40	Protective equipment has occasionally failed. Small machines in mining areas protected for safety reasons. Rotating machines generally connected to system through transformations or cables
19	Yes	Yes	Yes	Yes	80	
20	Yes	Yes	Yes	Yes	70	
21	No	No			50–75	New machines will be considered individually. No failures from lightning in 10 years
22				No	29	Past experience has not shown necessity for protection
23		Yes		Yes		Only one 16,500 kva unit protected
24	Yes	Some	?	Probably		Minimum arrester used. Tests in progress to determine proper functioning of protective equipment
25		Yes		Yes		
26		Yes		Yes		
27	Yes	Yes	Yes	Yes	70	
28				Yes		
29						Included in company number 30
30	Yes	No	Yes	Yes		
31				Yes		See Note (b)
32	Yes	No	Yes	Yes	26	
33	Yes	Yes	Probably	Yes		Would use reduced rating lightning arresters if solidly grounded. Most machines are connected to underground circuits
34	Yes	Yes		Yes		Recently adopted this practice. Future experience will dictate extensions
35	Yes	Yes	Yes	Yes		An additional 17 machines are connected to buses protected by lightning arresters. Capacitors used on multiturn coil machines only
36	Yes	Some	?	Probably		Minimum lightning arresters used. Tests in progress to determine proper functioning of protective equipment
37						Not sufficient exposure to require protection
38	Yes	Yes	Yes	Yes	30	Protection applied on basis of experience, exposure and size of unit
39		Yes	Yes	Yes		All units installed since 1938 are equipped and tests are in progress on others
40						Included in company number 44
41						Not sufficient exposure to require protection. Overhead lines carry arresters where they enter the station
42	No	Yes	?		25–30	Will be applied in future when recommended by manufacturer
43						Usual substation lightning arresters considered sufficient
44		No			45	High side arresters and ground wires considered sufficient
45	No	No				
46			No	No		Units operate ungrounded. Failure of small units connected to overhead lines expected
47	Yes	Yes	Yes	Yes		Capacitors used on multiturn coil machines
48	Yes	No		Some	50–60	Future installations to be made when justified
49				Yes		
50						No large rotating equipment
51	Yes	Yes	Yes	Yes	45	
52	Yes	No	Yes	No	10	All units directly connected to overhead lines are protected
53	Yes	No	Yes	Yes		Directly connected to overhead only
54	No	No	No	No	43	Bus or line arresters considered sufficient

a. No arbitrary rating. Protection determined by exposure, importance of load served, cost of repairs.

b. Lightning arresters always used on machines where connected to overhead circuits unless these circuits are in substations remote from the machine. Capacitors have been added to the lightning arresters where troubles have occurred. Protection of synchronous condensers (7,500 kva and up) has consisted of capacitors and this will be increased where overhead lines are involved.

considerably; however, the use of protective devices has, in general, reduced the number of failures.

4. The majority of the companies favored the use of a lightning arrester and capacitor. However, dependent upon conditions, the practice of using one method only does not generally hold. This summarizes as follows:

(a) Using lightning arrester only	3 companies
(b) Using capacitor only	0 companies
(c) Using lightning arrester and capacitor	23 companies
Using (a) or (b)	1 company
Using (a) or (c)	13 companies
Using (b) or (c)	1 company
Using (a) or (b) or (c)	1 company

5. The practice of using lightning arresters of reduced rating where the machine neutral is solidly grounded is followed by 21 companies. Six companies do not do this and others did not answer the question specifically.

6. Basically the question of applying lightning protection should be determined by possible exposure. Consequently, the idea of protecting machines which are directly connected to overhead lines seems to be generally prevalent. However, there is some divergence of opinion where these lines are connected to buses or where connection is made through cables to transformers which feed a bus that is protected by lightning arresters. For equipment directly connected to overhead lines, 27 companies installed protection, 9 did not. For equipment connected through transformers, 23 companies installed protection, 14 companies did not, and 6 companies installed protection in certain locations only. There were 43 companies that replied to this question and of these, included in the foregoing summary, 13 companies installed protection in either case and 4 companies in neither case.

7. In answer to the question as to whether this practice has been worthwhile, 32 companies answered the question with 21 affirmative answers, 4 negative, 2 probably, and 5 questionable until further tests were made, which tests are now in progress.

8. As to whether the companies expected to apply more of this equipment in the future, 45 companies replied. A marked tendency toward installing protection was evidenced by 33 companies definitely expecting to continue this work, 4 more would probably do so, 3 where it appeared to be justified, and only 5 replying in the negative.

9. The isokeraunic levels vary from about 80 thunderstorm days per year to the very low levels found on the Pacific Coast. There seems to be little correlation between these values and the extent of protection for rotating machines of the type mentioned herein.

Conclusions

At the present time past experience seems to be one of the major criteria for installing lightning protection on rotating a-c machines. Exposure conditions rather than size is a determining factor. The general trend seems to favor more of such protection and to lean toward the use of arresters and capacitors in combination. The results of tests now in progress should do much to clarify the situation in doubtful cases.

Discussion

E. H. Grosser, (Commonwealth Edison Company, Chicago, Ill.): This paper is of considerable interest in showing, from an analysis of the operating records of a large number of utilities, a definite justification for the lightning arrester protection of rotating machines.

The record presented shows a marked and consistent reduction in lightning failures where protective measures have been applied. Of 37 companies reporting the use of lightning protection on rotating a-c machines, 20 had no failures, or practically none, either before or after installing protective equipment, and two companies gave no report on failures. The remaining 15 companies, without exception, reported definite reductions in lightning failures after lightning arrester protection was installed. For eight companies, a complete elimination of failures resulted and for seven companies, assuming that the data given for before and after conditions covered comparable periods of service, there was a reduction in lightning failures of from 50 to 92 per cent of the previous rates. For all 15 companies, the average reduction amounted to 87 per cent of the failures before installing lightning protection.

Since Chicago practice and experience were not covered in the paper, it might be worthwhile to mention them here. Our generation is at either 12 or 22 kv and outgoing lines at generated voltage are, in all cases, underground cable lines. At transmission voltages (33, 66, 132, and 220 kv) the generators are separated from transmission lines by transformers. Lightning arresters are installed at the station end of all overhead transmission lines, except those with long cables between the station and the overhead line. With the single exception of a 75,000-kva synchronous capacitor connected to a 220-kv overhead line through a transformer, none of our rotating a-c machines are provided with lightning protection. In operation, there have been no generator failures attributable to lightning.

Edward Beck (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The report on lightning protective equipment for rotating a-c machines represents an appreciable cross section of the practices and experiences of the utilities. The report states that no data from Public Power Projects are included, whose experience would be of additional interest.

It should be recognized that there is a large and still growing volume of machine protection installed by industries such as steel mills, mining companies, pipe line pumping stations, and the like. The circuits are often exposed to severe lightning and sometimes handicapped by difficulties in obtaining low-resistance grounds. Protection is frequently applied to motors of relatively small horsepower. The economies in maintenance and loss of service have apparently been well established. A similar survey among these industrial users would be of interest to the electrical industry as a whole and the industrials in particular. We suggest that such a survey be planned for the future.

In Table I, under "Remarks," mention is made several times that tests are in progress to determine proper functioning. The nature of the tests and the instruments used to accumulate data would be of interest.

S. B. Howard (General Electric Company, Pittsfield, Mass.): The experience data on the use of lightning protective equipment for rotating a-c machines which Mawson's group has so ably brought to the attention of the industry, should do much to remove any doubt as to the value of such equipment in reducing machine failures attributable to lightning.

The data contained in columns 5 and 6 of Table I are particularly illuminating. Out of 15 companies reporting lightning failures prior to installation of protective equipment, 9 reported no failures where the equipment was applied, 5 reported from 50 to 90 per cent less failures and 1 reported "no failures of importance."

It should be most gratifying to all advocates of lightning protective equipment for rotating machines to note the justification of their recommendations by such excellent service experience.

Expulsion-Type Lightning Arresters' Impulse Spark-Over Volt–Time Characteristics

AN AIEE COMMITTEE REPORT

THIS REPORT presents the impulse spark-over volt–time characteristics of distribution lightning arresters of the expulsion type, as they are currently available. These arresters, rated from 3 to 15 kv inclusive, are covered by AIEE Standard 47 issued for trial use in December 1945. In that Standard several performance characteristics are enumerated, and the methods of determining the characteristics are described. Although all of the performance data described in the Standard are not yet available, it is thought desirable to present to the industry the available information on the impulse spark-over characteristics that may be expected, especially since in this type of lightning arrester the impulse spark-over characteristic is the most significant protective one and since Standard 47 is proposed for trial use only.

It is expected that at a later date, when additional information is available and a standard has been adopted, a subsequent report will be issued to include performance data on all the characteristics enumerated in the Standard.

The data in this report have been compiled from information supplied by seven manufacturers. The data pertain to lightning arresters as now manufactured and do not necessarily apply to older types. The present report covers only those lightning arresters available as separate pieces of equipment, as distinguished from those supplied as integral parts of other apparatus, such as self-protecting distribution transformers.

The average curve for each rating is derived from the manufacturers' average impulse spark-over volt–time characteristic of the complete lightning arrester including any integral or separate air gap. Tests were made using a 1.5x40-microsecond wave of the polarity giving the highest spark-over voltage. The front of wave spark-over at 100 kv per microsecond per 12 kv of rating is indicated by a dotted line to the curve for each rating. Each manufacturer also specified the tolerance applicable to his average curve. The characteristics for all manufacturers including tolerances fall within the tabulated maximum and minimum values at critical spark-over. Other points on the curve have a proportionate range from maximum to minimum. For the industry, the maximum deviations from the average curve are plus 58 and minus 49 per cent, but the tolerance permitted by any one manufacturer does not exceed plus or minus 25 per cent on his average curve.

The data in this report apply to the several available types of expulsion lightning arresters. To make the proper application of one of these, its impulse spark-over characteristic should be compared with the impulse withstand voltage strength of the insulation to be protected to insure that there is a satisfactory margin of protection.

Figure 1. Average impulse spark-over volt–time characteristic of 3-to-15-kv expulsion lightning arresters

Dotted lines indicate the standard front of wave test

Table I. Expulsion-Type Lightning Arresters' Critical Spark-Over

1.5x40-Microsecond Wave

Lightning Arrester Rating	Kv—Crest		
	Minimum	Average	Maximum
3	19	29	40
6	23	41	65
9	29	53	79
12	36	61	71
15	40	70	87

Paper 48-79, recommended by the AIEE protective devices committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted December 1, 1947; made available for printing December 8, 1947.

This report was prepared by a working group of the AIEE lightning protective devices subcommittee of the protective devices committee (power group), under the sponsorship of A. M. Opsahl (M'41).

Underexcited Operation of Turbogenerators

C. G. ADAMS
ASSOCIATE AIEE

J. B. McCLURE
MEMBER AIEE

OPERATION of turbogenerators at high-power factors and even extending into the leading region is increasing. This trend is due in some cases to the location of large steam-electric stations remote from the load and the transmission of their outputs at high voltage. In other cases, it is due to the application of corrective reactive kilovolt-amperes in the subtransmission and distribution areas of the system, or the use of high-voltage cable in the transmission system. These conditions are a natural result of system growth and economic pressure to more effectively use the generation and transmission equipment in the supply of electrical energy.

This paper reviews underexcited operation of turbogenerators from the standpoint of limits imposed by system stability and the application of lower excitation limits on voltage regulators. Results are shown for a typical turbogenerator operating on an average system. A method for readily estimating the stability limits for other machine and system characteristics is included in the Appendix.

It is hoped that in this way reassurance will be given to those who find high-power factor operation of generators desirable in planning their normal system expansions.

Conclusions

1. Modern turbogenerators manufactured by the company with which the writers are associated may be operated successfully in the range of 60 per cent underexcited reactive kilovolt-amperes at zero kilowatt load to 30 per cent underexcited reactive kilovolt-amperes at rated generator kilovolt-amperes. Sufficient leading reactive capacity is thereby made available to supply most system demands.

2. For most practical system conditions, operation as indicated before retains adequate steady-state stability margins.

3. Voltage regulator control with an automatic lower limit rationally permits a greater utilization of leading reactive capability than does manual control of excitation.

Simplified Analysis of a Typical System

Figure 1 shows a one-line diagram of the generator or station, under consideration, supplying load to its system. Figure 2 shows the general relations between the system, machine terminal, and machine excitation voltages. Their specific relation for various conditions will be discussed later. The following conditions have been assumed.

1. The generator is rated 0.8 power factor, 0.9 short-circuit ratio (SCR). Maximum turbine output equals rated generator kilovolt-amperes which is 1.0 per unit.

2. The equivalent synchronous reactance of the generator is equal to the reciprocal of short-circuit ratio.

3. The system is represented by an equivalent reactance X_s.

4. Resistance in the circuit is neglected.

5. Since most turbogenerators have a cylindrical rotor, pullout power is assumed to occur when there are 90 degrees between the generator excitation voltage and the equivalent system voltage.

These assumptions simplify the determination of operating characteristics while not greatly affecting the accuracy of the results over a wide range of system conditions.

Effect of Generator Saturation

Generator saturation increases the steady-state pullout power over that which would exist if there were no saturation. An equivalent synchronous reactance equal to the reciprocal of the short-circuit ratio has been assumed in order to approximate the saturation effect. Results, when using this approximation, have been found to closely agree with those obtained by other more detailed methods described in reference 1, particularly for the condition of pullout at low excitation.

Representation of System by an Equivalent Reactance

Representation of a system by an equivalent reactance is fairly well known. It is simple and produces practical results. Based on generator rating, a stiff system may have an equivalent reactance in the order of 15 per cent. Systems involving long power transmission may approach a value of 40 per cent.

A fairly good approximation to the equivalent system reactance may be obtained in the following manner. In most cases the short circuit kilovolt-amperes for circuit breaker application is known at the generator bus. Reduce this kilovolt-amperes by the amount contributed by the generator in question. Divide twice the rated generator kilovolt-amperes by the reduced short circuit kilovolt-amperes. The result is approximately the system equivalent reactance in per unit. A more accurate method is to set up the system on a calculating board and insert a synchronous reactance of all generators equal to the reciprocal of their short circuit ratios. Find the reactance looking into the system at the entry point of the generator being studied. The latter method is more complicated but more

Paper 48-81, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 10, 1947; made available for printing December 4, 1947.

The authors wish to acknowledge the particularly helpful suggestions and constructive criticism of R. B. Bodine, C. Concordia, S. B. Crary, R. H. Freiburghouse, H. D. Huntley, H. F. McCullough and H. D. Taylor of the General Electric Company.

Figure 1. One line diagram of system

accurate. Since steady-state pullout powers are not affected greatly by small variations in equivalent system reactance, not much effort can be justified in obtaining an extremely accurate system representation.

Generator Operating Limits

Figure 3 is a plot of reactive kilovolt-amperes and kilowatt output for the assumed generator operating at its rated terminal voltage. Positive reactive kilovolt-amperes is supplied by an overexcited generator. The circle *ABCE* is the well known limit due to rated line armature current. The curve *IB* is the limit due to rated field current. Area *CGKL* is suggested for the setting of the operating range of lower excitation limits being applied on modern voltage regulators. Stability limits for two values of equivalent system reactance are shown by curves *JF* and *DF*. (See Appendix I for curve derivation.)

The tendency for heating in the end structure of the armatures of turbogenerators with rated armature current and low field current was recognized as long ago as 1920. Up to that time, all machines were built with magnetic materials in the end structures, which contributed to heating in these portions of the machine. The operation in the underexcited region of machines built prior to about 1925 should be approached advisedly and preferably should be checked by temperature measurement under actual operating conditions. As a result of design progress, experience and tests indicate that modern turbogenerators manufactured by the company with which the writers are associated operate successfully in the suggested area for voltage regulator lower limit setting without excessive temperatures and retain adequate stability margins. It should be recognized that for hydrogen-cooled machines, operation with increased hydrogen pressure permits a higher kilovolt-ampere output under comparable operating conditions.

Manual Control Operation

Figures 4 through 9 illustrate the factors influencing pullout power when the generator excitation is manually controlled. Referring to Figure 2, the generator excitation voltage E_d and the system voltage E_s are determined so that with the initial loading there is rated voltage at the generator terminals, except for Figure 6 for which the initial generator voltage is varied. Holding E_d and E_s at their initial values, the maximum pullout power is assumed to occur when these voltages are at 90 degrees. Figures 4 through 9 show the pullout power that can be developed with the excitation and system voltages unchanged from their initial values for different initial loads, initial power factors, system equivalent reactances, generator short-circuit ratios, and initial generator terminal voltages.

Figure 4 shows the pullout power versus power factor for several constant kilowatt loads. The power increment between the curves and the dashed line at the kilowatt loading for which the curve is drawn is the power that may be picked up under the condition of no change in excitation or system voltage from their initial values. These power increments have been plotted against power factor in Figure 5. The effect of changing generator terminal voltage on allowable power increment is shown in Figure 6. Pullout power as function of initial kilowatt load for different initial power factors is shown in Figure 7. The curves of Figure 8 illustrate the effect of system reactance on pullout power. The effect of generator short-circuit ratio on pullout power is shown in Figure 9. Figure 10 shows the variation in pullout power produced by a change in system equivalent reactance for a low short-circuit ratio generator.

The question of primary importance in the system operation is the ability of its component parts to endure the normally encountered emergencies. Generators will be required to quickly pick up load in case a generator is tripped off; in case a major tie-line opens; or if a high rate of system load increase is encountered. For most system conditions, it can readily be determined what load increases may be expected on the several generators as a result of any emergency. This determination should take into account any

Figure 3. Rated voltage generator circle diagram
0.8 power factor cylindrical rotor generator
Short circuit ratio of generator = 0.9
Equivalent X_d = 1/TCR = 1.111
Maximum turbine output = generator kilovolt-amphere

Figure 2. System vector diagram

Figure 4 (left). Pullout power versus power factor at constant kilowatt loads

Figure 5 (above). Limiting value of power increment for stability versus initial load power factor for different initial loads

limitations in boiler capacity; speed governor characteristics; and the action of any load-limiting devices which may be employed in the control of the prime-mover input. In this way an estimate can be made of excitations which should be maintained for machines on manual control in order that they may pick up their expected share of load without loss of synchronism.

For a typical machine, Figure 4 shows that a machine initially loaded to 80 per cent kilowatts at 0.9 power factor lead can pick up about 7 per cent in power before going out of step. It also shows that with 80 per cent initial kilowatt load at 1.0 power factor, the pullout power exceeds the turbine capability. Margins in permissible power increment are small in the higher load regions at 0.8 power factor leading.

If the generator load increase for the most severe system disturbance is known, the required power factor for the initial kilowatt load may be obtained from Figure 5. The dashed curve AB on Figure 5 is drawn through the points where the initial kilowatt load plus the permissible power increase is equal to the maximum turbine capability. If operation is maintained in the region to the right of curve AB, the generator will not pull out within the turbine rating. This type of operation would be most conservative. It is also apparent from Figure 5 that with an initial 20 per cent kilowatt load at 0.9 leading power factor, a 50 per cent load increase can be accepted by the generator before instability is encountered.

In practical operation, the generator voltage will probably be less than rated when the machine is required to absorb large amounts of leading reactive kilovolt-amperes. Figure 6 shows the effect generator terminal voltage has on permissible power increments for power factors between 0.95 lag and 0.95 lead. The desirability of voltage regulator control when operating in the leading region and at low generator terminal voltage is emphasized by the reduction in allowable power increment as the generator voltage decreases. At 0.95 leading power factor and 0.8-kw load, the power increment at 90 per cent generator voltage is one-half its value at rated generator voltage.

In Figure 7 the difference between the straight line at 45degrees with the horizontal axis and the curves may be interpreted at any kilowatt loading as the permissible power increment at that initial loading. The increase in the power increment as initial power factor goes from the leading to the lagging region is evident. To accept the maximum turbine output, an

Figure 6. Limiting value of power increment for stability versus generator terminal voltage

initial 40 per cent kilowatt load may be carried at 0.8 lagging power factor and an initial 75 per cent kilowatt load at 1.0 power factor.

In Figures 8 and 9 the permissible power increment is again the difference between the curves and the straight 45 degree line. The change in pullout power for an initial 1.0 power factor load resulting from doubling the equivalent system reactance is shown in Figure 8. Figure 9 shows the effect of decreasing generator short-circuit ratio from 0.9 to 0.6. Qualitatively from Figures 8 and 9, the conclusion may be drawn that generator pullout power is not greatly affected by small changes in its short circuit ratio or in system stiffness.

Voltage Regulator Operation

When the excitation of a machine is under the control of a voltage regulator, adjusted to maintain rated voltage at the machine terminals, the generator will stably accept the maximum turbine output in any practical case. The curves in Figure 10 assume that the excitation system has a ceiling voltage 50 per cent in excess of the required slip ring voltage at the rating of the main generator. This is equivalent to having an exciter of 300-volt ceiling and rated generator slip ring volts of 200 which is representative of present day practice. Terminal voltage of the generator is assumed to be 1.0; the exciter is at ceiling; 90 degrees exists between machine excitation voltage and equivalent system voltage. For ceiling excitation on the generator, it appears from Figure 10 that the available generator pullout power is about twice the maximum turbine output for X_s from 20 to 40 per cent corresponding to the average system under normal conditions. It is realized that these torques are seldom required or seldom exist and to that extent are somewhat fictitious, but at the same time it does give an indication of the margins which are available through the automatic control of excitation, which are available to meet emergency system conditions.

Some voltage regulators permit the

Figure 7. Pullout power versus initial load at different power factors

Figure 8. Pullout power versus initial kilowatt load for different external reactance

adjustment of the lower limit of excitation as a function of turbine kilowatt load or of the generator kilovar output. Area *CGKL* on Figure 3 suggests a range for the setting of these limits which will in most cases leave a considerable margin between system requirements and machine capability. Manual control operation in this region allows the generators to accept a reasonable load increase before pulling out of step; however, it should be realized that Figure 3 represents conditions for rated generator terminal voltage, and that allowable power increments are reduced as the generator voltage is decreased. Voltage regulator control rationally permits operation closer to the steady-state stability limit and possibly beyond those shown by operation in the "dynamic" stability region. However, operation below the line *GC* on Figure 3 should be approached advisedly from the system,

Figure 9. Pullout power versus initial kilowatt load for different short-circuit ratios

voltage regulator, and machine standpoints

Transient Stability

Since the voltage behind transient reactance is not affected greatly by power factor at rated terminal voltage, transient stability limits are almost unaffected by initial loading conditions. Voltage regulators with usual rates of response and ceilings affect these limits by a rather minor amount. Of course, transient synchronizing torques are high as compared to the steady-state stability limits and are of importance in determining whether synchronism will be lost after a system short circuit has been cleared.

For a turbogenerator on an average system operation at unity or in the leading power factor region will have a small effect upon transient limits. With manual control of excitation, generators should be operated with sufficient excitation so that they can stably accept their load increment after the transient phase is over. Voltage regulators can adjust excitation rapidly enough during the transient period, so that any load may be assumed up to the generator rating. Voltage regulator control permits operation closer to the steady-state stability limit.

Nomenclature

Unit Kva = unit kilovolt-amperes is the generator rated kilovolt-amperes which is equal to the maximum rated turbine output

Figure 10. Pullout power versus external reactance

P = real power in per unit
Q = reactive kilovolt-amperes in per unit
E_d = generator excitation voltage which is proportional to generator field current. Unit excitation voltage produces the field current required at rated no load voltage on the generator saturation curve
E_t = generator terminal voltage in per unit of rated generator voltage
E_s = equivalent system voltage in per unit of rated generator voltage
SCR = generator short circuit ratio is the ratio of field current at no load rated voltage on generator saturation curve to field current that produces rated generator armature current with armature short circuited
X_d = equivalent generator synchronous reactance in per unit which is assumed equal to reciprocal of generator short circuit ratio
X_e = equivalent system reactance in per unit of generator base ohms. Base ohms of generator equals rated generator line to neutral voltage divided by rated generator armature current
I = generator armature current in per unit of rated armature current
θ, β, α = angles defined by Figure 2

Appendix I

Figure 3 shows approximate reactive and real power limits on the basis of rated voltage at the machine terminals. These limits may be readily estimated in the following manner:

Rated Armature Current Limit

The vector power is given in equation 1 for the convention that an overexcited generator supplies positive lagging reactive power to its connected system†

Figure 11. Circle in vector notation

$$\mathbf{P}+j\mathbf{Q}=\mathbf{E}_t\mathbf{I}^* \tag{1}$$

Referring to Figure 2, the generator terminal voltage in vector notation is

$$\mathbf{E}_t=E_te^{j\beta} \tag{2}$$

and the generator armature current is similarly

$$\mathbf{I}=Ie^{j(\beta+\theta)} \tag{3}$$

The conjugate of the current is

$$\mathbf{I}^*=Ie^{-j(\beta+\theta)} \tag{4}$$

The vector power is found by substituting equations 4 and 2 in equation (1).

$$\mathbf{P}+j\mathbf{Q}=E_te^{j\beta}Ie^{-j(\beta+\theta)} \tag{5}$$

or

$$\mathbf{P}+j\mathbf{Q}=E_tIe^{-j\theta} \tag{6}$$

Equation 6 for the condition that $E=1.0$ and $I=1.0$ (rated voltage at the generator terminals and rated current in armature), represents a circle with its center at the origin with a radius of $E_tI=1.0$. This is circle $ABCDE$ on Figure 3. When the current lags the terminal voltage, the imaginary part of equation 6 is positive since the angle θ is negative. This corresponds to overexcited operation.

Rated Field Current Limit

The maximum field current is determined by the field current required when the machine is carrying rated kilovolt-ampere at rated power factor. Referring to Figure 2 and determining the vector power in the same manner:

$$\mathbf{P}+j\mathbf{Q}+\mathbf{E}_t\mathbf{I}^* \tag{7}$$

$$\mathbf{I}=\frac{\mathbf{E}_d-\mathbf{E}_t}{jX_d}=\frac{E_de^{j\alpha}-E_te^{j\beta}}{jX_d} \tag{8}$$

$$\mathbf{I}^*=\frac{E_de^{-j\alpha}-E_te^{-j\beta}}{-jX_d} \tag{9}$$

$$\mathbf{P}+j\mathbf{Q}=E_te^{j\beta}\left[\frac{E_de^{-j\alpha}-E_te^{-j\beta}}{-jX_d}\right] \tag{10}$$

Multiplying out equation 10

$$\mathbf{P}+j\mathbf{Q}=\frac{E_tE_d}{X_d}e^{j\left(\beta-\alpha+\frac{\pi}{2}\right)}-j\frac{E_t^2}{X_d} \tag{11}$$

For constant values of E_d and E_t, equation 11 is a circle with its center on the negative reactive axis at E_t^2/X_d and with a radius of E_tE_d/X_d. Applying to Figure 3, the center of circle IB is on the negative reactive axis at $E_t^2/X_d=1/1.111=0.9$, and its radius is $E_tE_d/X_d=(1)(1.89)/1.111=1.70$. Circles for other constant field currents than rated may be easily drawn by keeping the same center and varying the length of the radius in proportion to the field current.

Steady-State Stability Limit

The limiting pullout power is taken to be that power flow existing when E_d and E_s are at 90 degrees and $E_t=1.0$. For this case taking E_t along the real axis,

$$\mathbf{E}_d=E_de^{j\alpha}=E_de^{j\pi/2}=jE_d \tag{12}$$

$$\mathbf{E}_s=E_se^{j\beta} \tag{13}$$

$$\mathbf{I}=\frac{\mathbf{E}_d-\mathbf{E}_t}{jX_d}=\frac{jE_d-E_te^{j\beta}}{jX_d} \tag{14}$$

$$\mathbf{I}^*=\frac{-jE_d-E_te^{-j\beta}}{-jX_d}=\frac{E_d-jE_te^{-j\beta}}{X_d} \tag{15}$$

$$\mathbf{P}+j\mathbf{Q}=\mathbf{E}_t\mathbf{I}^*=E_te^{j\beta}\left[\frac{E_d-jE_te^{-j\beta}}{X_d}\right] \tag{16}$$

$$\mathbf{P}+j\mathbf{Q}=\frac{E_tE_de^{j\beta}}{X_d}-j\frac{E_t^2}{X_d} \tag{17}$$

From the geometry of Figure 12

$$\sin\beta=\left[\frac{X_e}{X_d+X_e}\right]\frac{E_d}{E_t} \tag{18}$$

or

$$E_d=\left[\frac{X_d+X_e}{X_e}\right]\sin\beta E_t \tag{19}$$

Eliminating E_d from equation 17 by using equation 19

$$\mathbf{P}+j\mathbf{Q}=E_t\left[\frac{X_d+X_e}{X_eX_d}\right]\sin\beta e^{j\beta}-j\frac{E_t^2}{X_d} \tag{20}$$

By using the relation developed in Appendix II, equation 20 is:

$$\mathbf{P}+j\mathbf{Q}=E_t\left[\frac{X_d+X_e}{2X_eX_d}\right]e^{j(2\beta-\pi/2)}+jE_t^2\left[\frac{X_d+X_e}{2X_eX_d}-\frac{1}{X_d}\right] \tag{21}$$

Equation 21 is the equation of a circle with its center on the reactive axis at

$$E_t^2\left[\frac{X_d+X_e}{2X_eX_d}-\frac{1}{X_d}\right]$$

and a radius of

$$E_t^2\left[\frac{X_d+X_e}{2X_eX_d}\right]$$

In Figure 3, the center of circle DF is at

$$(1)^2\left[\frac{(1.111+0.2)}{2(0.2)(1.111)}-\frac{1}{1.111}\right]=2.045$$

on the positive reactive kilovolt-ampere axis and has a radius of

$$\frac{(1)^2(1.111+0.2)}{2(0.2)(1.1111)}=2.945$$

† See Nomenclature for definitions of symbols.

* Asterisk adjacent to bold face type indicates a conjugate vector.

Appendix II

Referring to Figure 11, a circle is described by a vector when its scalar magnitude remains constant and its angle completes 360 degrees. A circle passing through the origin with radius a and center on the imaginary axis is represented by equation 22.

$$r = ae^{j(2\theta - \pi/2)} + ja \qquad (22)$$

From the geometry of Figure 12, the scalar magnitude of r is that shown in equation 23.

$$r = 2a \sin \theta \qquad (23)$$

The angle subtended at A by the arc OB is 2θ, where θ is the angle that the radius vector makes with the real axis. Therefore in vector notation equation 24 shows two equivalent forms for a circle with its center at a on the

Figure 12. Vector diagram at pullout

$$r = 2a \sin \theta e^{j\theta} = ae^{j(2\theta - \pi/2)} + ja \qquad (24)$$

imaginary axis and radius of a. The center of the circle may be shifted up and down the imaginary axis by the simple addition of another vector.

Discussion

M. D. Ross (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors are to be congratulated on giving a very interesting treatment of stability limits in the underexcited region of operation. The capability curves included in the AIEE standards for the larger machines were proposed to the committee by McClure and have been a valuable addition to the standards in explaining the load limits of the turbine generator. Figure 3 of the present paper expands that diagram to the underexcited region.

In discussing the limitations of the generator so far as heating of the end zones is concerned the authors, in the second paragraph under the heading "Generator Operating Limits" would infer that improvements in the design included the use of non-magnetic materials for the stator end plates or clamping flanges and perhaps for the retaining rings of the rotor. It might be of interest to state the experience of the company with which I am associated in which we have always used magnetic materials for stator end plates and rotor retaining rings and continue to do so today.

For a given load at leading power factor the flux in the end zones is largely governed by the long air gap between the rotor and the stator end plates in the end of the stator core. This flux, which rotates with its rotor, passes from one pole of the rotor to the end of the stator, passes circumferentially around the stator, out the opposite side of the stator to the opposite pole and through the rotor to its starting point. If a nonmagnetic end plate is used a considerable portion of this flux passes through the end plate into the end laminations of the core, producing losses in these parts. Where a magnetic end plate is provided, this flux passes around the stator in the end plate in a thin skin on the surface of the solid iron. It is our practice to use alloy steel which will reduce the losses in the magnetic end plate to a reasonable value. In this case practically no flux enters the laminations back of the end plate.

We tested a 25,000 kva hydrogen cooled, 3,600 rpm generator about a year ago at a number of armature current values at zero power factor underexcited, and found the temperature rise of the stator end plates with zero field and 90 per cent armature current was below 60 degrees centigrade as compared with an American Standards Association temperature limit for such parts of 70 degree centigrade rise. While this temperature rise will not necessarily be duplicated in all sizes of machines, we have to date found no difficulty in building the largest machines with end plates and retaining rings of magnetic materials.

Table I. Data on Tests to Determine Extent of Armature Lamination Finger Heating

Megawatts	Field Amp	Power Factor	Temperature Rise, Degree Centigrade: Armature	Field	Hottest Finger
42.3	470	0.97 Lag	33.7	50.5	59.5
42.8	350	0.97 Lead	33.0	36.5	84.7

Note: Armature temperature by embedded detector. Field temperature by change in resistance.

Machine rated 44,705-kva 0.85-power factor, 13,200 volts

Matthew S. Schneider (The Cincinnati Gas and Electric Company, Cincinnati, Ohio): The authors offer a word of caution in regard to the operation of machines made prior to 1925 at low excitation. An investigation of the insulation failure in one of these older machines led to the conclusion that extensive finger heating was the cause.

The magnetic structure mentioned consists of armature lamination clamping fingers of magnetic material held in place by a ring of the same material. The fingers are so situated in the machine that they are in the flux area of the main field retaining ring. The amount of flux through the fingers is a function of the saturation of the ring due to d-c field current. The greater the field current the lower will be the flux in the fingers and the less the heating effect produced by iron losses. The maximum heating occurs where the a-c flux density is greatest, which in the machine that failed is at the center of the phase belts.

This local heating effect will not be observed in readings of the usual embedded temperature detectors and will be apparent only by flow of compound out of insulation adjacent to the hot fingers.

To determine the extent of this heating, tests were conducted on a machine which had identical characteristics as the one which failed. Thermocouples were inserted in the fingers to obtain actual temperatures. The data in Table I, giving the test results, show the extent of this heating.

Not only was the temperature in the clamping fingers higher than that of the other parts of the machine, but the rate of rise was also greater. The finger temperature change followed the field current change by a matter of seconds.

J. W. Batchelor (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The generator capability curve illustrated in Figure 3 of the paper for which the authors have presented an admirable derivation is quite useful to the designer and the application engineer. It is suggested that a derivation with a different approach might bring out some features which would make the information as useful to others as it has proved to us.

This derivation is based upon the concept of an unsaturated machine, as suggested by the authors, in which the no-load field current is equal to that of a machine with saturation. Thus, the reciprocal of the short circuit ratio equals the equivalent synchronous reactance. If the excitation for the synchronous reactance is designated as 1.0, the no-load excitation equals the short circuit ratio. These two values of excitation may then be added at the rated power factor angle to determine rated full load excitation.

Therefore, it is necessary to know power factor, short-circuit ratio and system reactance at rated kilovolt-ampere, to determine the per unit generator capability curve as shown in Figure 1 of the discussion. The curve ACF with center at H and radius equal to 1.0 represents the full load temperature limit of the armature. Full load field current may be determined by adding the field currents for no-load and synchronous reactance at the rated power factor angle. This is the triangle GHB and since GB is the full load field current, the curve BJ with center at G represents the maximum loading in the region where field temperature is the limit.

The steady-state stability limit is an arc

starting at G with center along the vertical axis, and with radius equal to $SCR/2+1/2X_s$, where X_s is the system reactance on the machine kilovolt-ampere base. The expression for the radius may be obtained by considering the condition for pullout at machine voltage and power factor equal to 1.0, and by solving similar right triangles. The expression derived by the authors may be reduced to this form. In the case of an infinite bus, the circle has an infinite radius, and the limit reduces to the line GE.

Once the capability curve has been established for full load conditions, it may be used for other operating conditions, by keeping the center for armature conditions at H and for field conditions at G. For example, with a hydrogen cooled turbine generator nominally rated at 0.5 pound per square inch gauge gas pressure, but operating at 15 pounds per square inch gauge the stator current may be increased 15 per cent and the field current increased 8 per cent. Thus, the radius HC is increased 15 per cent, and radius GB is increased 8 per cent. The intersection of these two circles is on an extension of the line HB. It should be noted that the per unit scale for field current is not necessarily the same scale as is used for kilovolt-amperes since one per unit field current is determined by the short circuit ratio.

J. B. Ward (Purdue University, Lafayette, Ind.): This timely paper will be very useful to engineers concerned with system operating and planning problems. The curves in the paper clearly show the influence of various factors upon operating limits at low excitation. It is the purpose of this discussion to examine more critically the simplified method of analysis used to derive these curves. The authors list the assumptions on which the method is based, but the conclusion that these do not seriously affect accuracy over a wide range of system conditions is not immediately obvious. At least the range of applicability is not clearly evident in the assumptions themselves, and a planning engineer might wonder, first of all, if his particular system and operating conditions would fall within the range referred to by the authors. In addition, rational decisions on safe operating margins which are based on stability calculations require some knowledge of limitations and potential errors inherent in the method used.

Figure 1. Generator rated voltage capability curve

Figure 2. Limiting power increment for generator (1) as a function of initial power factor at initial kilowatt loading of 0.5 per unit. All impedance and power quantities in per unit on machine (1) kilovolt-ampere rating

In connection with the third assumption of the list, the method of representing the system by an equivalent reactance for stability calculations is fairly well known, but perhaps is not as well understood. Basically it is an application of Thevenin's theorem, but unfortunately with the presence of speed governors, magnetic saturation, and other influences, power systems do not submit to rigorous application of linear network theory. With most of the reactance residing in the machine to be tested for pull-out limits and a relatively small amount in the equivalent system it seems logical to assume that system conditions would not seriously affect results. Nevertheless, it is desirable to know how much and in what direction the pull-out limits might vary with system conditions. This variation can be demonstrated to a certain extent by numerical examples based on equivalent circuits which represent a slightly less complete reduction of the system than the single equivalent reactance. As an illustration, the following examples are presented, giving some results for the relatively stiff equivalent reactance of 0.2 per unit which is discussed in detail in the paper as an average condition.

Consider first a metropolitan-type system in which the generating capacity is close to a concentrated load area. The other extreme of a remote station supplying power over a high-voltage transmission link is discussed later. Referring to the equivalent circuit in Figure 2 of the discussion, all generation except unit (1), the machine being studied, is combined into an equivalent generator as shown at (2). This assumption is valid if the load is almost evenly divided among machines of similar characteristics. The system load is combined also into a single equivalent load represented by a constant impedance Z. An additional step of paralleling Z and X_2 gives the equivalent reactance X_s of the system. In this circuit the magnitude of the system load and the relative loading of connected generating capacity are not entirely concealed. Upon specifying the terminal voltage and the initial loading and power factor of unit (1), the loading of the equivalent generator and the excitation voltages E_1 and E_2 can be determined. The pull-out power at constant excitation is obtained from the equation:

$$\text{Max. } P_1=\frac{E_1^2}{Z_{11}}\sin\alpha_{11}+\frac{E_1E_2}{Z_{12}}$$

where: Z_{11} = magnitude of the driving point impedance viewed from E_1

Z_{11} = magnitude of the driving point impedance viewed from E_1

$=X_1+X_2Z/(X_2+Z)$

Z_{12} = magnitude of the transfer impedance from E_1 to E_2

$=X_1+X_2+X_1X_2/Z$

Figure 3. Limiting power increment for generator (1) as a function of initial power factor at initial kilowatt loading of 0.5 per unit on (1) and with constant kilowatt loading on (2). All impedance and power quantities in per unit on machine (1) kilovolt ampere rating

$\alpha_{11} = 90° - \theta_{11}$

θ_{11} = impedance angle of Z_{11}

The curves of Figure 2 of the discussion show some results for an initial kilowatt loading on machine (1) of 0.5 per unit. The values assumed for this machine are: Rated power factor 0.8, *SCR* 0.9, $X_1 = 1/SCR$, initial terminal voltage 1.0 per unit. The various combinations of X_2 and Z shown with the four curves are chosen to give a value of 0.2 per unit for X_e in each case. All quantities are based on the kilovolt-ampere rating of machine (1).

Curve (a) is obtained by the simplified method presented in the paper. For curve (b) the load is 2.5 per unit, unity power factor, resulting in an initial kilowatt loading of 2.0 per unit on the equivalent machine. If X_2 represents generators with the same *SCR* as unit (1), this corresponds to nearly full load on the connected capacity. Curve (c) represents a different system in which the $0.5+j0$ load impedance corresponds to 2.0 per unit system load and results in a 1.5 per unit loading on the equivalent machine. This is a loading of approximately one third the connected capacity on the same basis. Curve (d) is for the same value of X_2 as curve (c) but with a system load at 0.9 power factor lagging. Note that all three curves lie above (a), indicating approximately the extent by which the simplified method described by Adams and McClure gives conservative results for these system conditions.

Next consider a system of the type illustrated in Figure 3 of this discussion. The machines represented by (1) and (2) supply power to a remote load center (Z) over a transmission system, and the generators at and beyond the load center are combined into an equivalent machine (3). Unit (1) represents the machine to be tested for pull-out limits and (2) the combined effect of nearby machines. If unit (1) is a 50-megawatt, 0.8 power factor machine, for example, the line reactance of 0.2 per unit corresponds to approximately 80 miles of double-circuit 132-kv line with transformer banks at each end. For simplicity resistance is neglected except in the load impedance. This system, viewed from the terminals of unit (1), again reduces to an equivalent reactance X_e of 0.2 per unit. Ratings of unit (1) are the same as in Figure 2.

Curve (a), obtained by the method of the paper, is included for comparison. The other curves show the maximum power increments which can be picked up by unit (1) from an initial kilowatt loading of 0.5 per unit with two different constant kilowatt loadings on (2). These results were obtained by means of an a-c network calculator. In the calculator set-up capacitive reactance was substituted for inductive reactance to avoid the inherent resistance of the inductive circuits. After adjustment to the desired initial conditions, machine (1) was advanced to the pull-out limit, with the power output of (2) and excitation voltages held constant. In this equivalent circuit there are many possible combinations of initial reactive power loadings on machines (2) and (3) for a given loading on unit (1). For purposes of comparison the reactive power was shifted from (1) to (2) as the power factor of (1) was varied, in order to keep the initial line loading and load bus voltage constant. In both curves the power factor of (2) was adjusted to approximately unity at the 0.9 lagging power factor condition on unit (1).

The kilowatt loading on (2) of 1.2 per unit represents half-load on the basis that the connected machines have the same *SCR* as unit (1). The maximum power increments are considerably less at lagging power factors than those obtained by the simplified method, but with a smaller discrepancy appearing at leading power factors. As the load on (2) is increased beyond this value the maximum power increments for (1) fall decrease rapidly since the system is approaching the steady-state stability limit. For 0.8 per unit kilowatt load on (2), a less severe condition, the curve conforms more closely with that of the simplified method, particularly in the leading power factor region.

For the conditions considered before, the single equivalent reactance representation yields sufficiently accurate results for most practical purposes at unity and leading power factors, which is the area of primary interest in the present paper. The simplified method probably should be applied with caution to initial loadings in the lagging region when long, heavily loaded transmission systems are involved. The applicability to other operating conditions and types of systems can be checked in a similar manner.

W. H. Osterle (West Penn Power Company, Pittsburgh, Pa.): As I understand this paper, the authors have taken the mathematical equation $E_d E_t / X_d + X_e$ and for different loads and various power factors with different values of external impedance (X_e) calculated the pull-out power, using X_d, the reciprocal of the short-circuit ratio, and E_t, terminal voltage of the machine, as unity. Have the authors any experimental data or results of any actual cases of generator static instability that can be plotted on any of these curves to see how near actual cases compare?

Will the authors elaborate a little on the subject of "end structure heating with low field current?" How serious is this condition and what information is needed to detect its presence?

Under the section Voltage Regulator Operation the following sentence appears:

> "When the excitation of a machine is under the control of a voltage regulator, adjusted to maintain rated voltage at the machine terminals, the generator will stably accept the maximum turbine output in any practical case."

I understand this to mean that a generator under the control of a voltage regulator cannot become unstable when operating at rated voltage. (1 per unit.) Suppose the generator were operating at a voltage of say 0.95 or 1.05 per unit, would this have any effect on its stability characteristics?

C. G. Adams and J. B. McClure: The authors welcome the supporting data and calculations submitted in several of the discussions. In general, they serve to justify some of the assumptions and emphasize limitations on older turbogenerators in the underexcited region.

Ross has presented valuable data regarding zero power factor operation of modern generators which his company manufactures. With regard to detailed generator design to avoid serious stator end heating, there are several design approaches. As well as the one outlined by Ross, the use of nonmagnetic end materials and step backs in the stator core is successful.

Schneider's data clearly show that serious heating can develop at leading power factors in older machines. Our tests also show that the finger temperatures rapidly follow changes in loading. When underexcited operation is contemplated on older machines in service, field tests provide the best data on which to base future operation.

Ward's discussion supports the assumption of a generator equivalent reactance equal to the reciprocal of its short circuit ratio, especially at leading power factors. Obviously the purpose of this assumption is to simplify calculations while retaining reasonable accuracy. In actual operation, borderline cases should be approached only when using automatic control of excitation.

The use of modern voltage regulators eliminates the significance of incremental power limits established for manual control of excitation.

We refer Osterle to data presented by other discussers and to Figure 6 in the paper for the effect of operating at other than rated voltage. Voltage regulator control will increase system stability for steady-state load changes.

Batchelor presents another method of arriving at Figure 3. In the use of this figure, the assumption of rated generator voltage should be borne in mind.

Rototrol Excitation Systems

J. E. BARKLE

C. E. VALENTINE
MEMBER AIEE

FOR purposes of discussion, an excitation system for a synchronous machine may be considered as including all equipment necessary to regulate the a-c voltage and supply excitation to the field of the a-c machine. This will include the voltage regulator and its auxiliary devices, the d-c machines for supplying excitation to the a-c machine and provision for manual control of the a-c machine output. The development of the Rototrol amplifier as a portion of the a-c machine excitation system has brought about radical changes in all three parts of the excitation system.

Rototrols for excitation systems are available having single-stage or two-stage amplification. The principle of operation of both types has been described previously along with analyses of their use in several industrial applications.[1,2] The choice between one-stage or two-stage amplification depends on the energy available in the control circuit and the total power output required. The two-stage Rototrol is capable of producing sufficient power at its terminals to excite the field of the largest steam-driven generator with approximately the same controlling energy used with the single-stage machine. Therefore, the two-stage Rototrol can be used as either a pilot exciter or a main exciter.

The Rototrol is similar in design and appearance to a conventional d-c machine. Control and amplification are obtained through the use of several stator fields.[2] Mechanical construction is essentially the same as any conventional d-c machine of similar rating and speed. The physical size of a Rototrol pilot or main exciter is substantially the same, or slightly larger than conventional machines due to more field windings in the stator structure and due to operation with an unsaturated magnetic circuit. The air gaps of both types of machine are of normal size. Either one or two stages of amplification are supplied in a four-pole machine; therefore, the Rototrol can be direct-connected to the shaft of any generator operating at 1,200, 1,800, or 3,600 rpm. In providing excitation for slower speed machines, the Rototrol must be separately driven at higher speed to secure a smaller physical size unit, which will not require excessive control energy.

The following discussion explains how the Rototrol pilot exciter is used in the excitation systems of various types of a-c machines. Since the pilot exciter and main exciter are only part of the excitation system, the various types of voltage regulators and limiting devices are included to make the discussion complete. The Rototrol direct-connected main exciter is a radical departure from previous practices in providing excitation for large turbine generators. A complete description and analysis of performance is being presented in a companion paper[3] and only brief mention made in the following discussion.

Turbine Generators

Rototrol Pilot Exciter with Single-Field Main Exciter

The simplest form of Rototrol pilot exciter as it may be used with a turbine generator is shown schematically in Figure 1. Since the Rototrol is a high-speed machine and of normal d-c machine construction, the a-c generator, main exciter and pilot exciter are all driven by the same shaft at 1,200, 1,800, or 3,600 rpm (for a 60-cycle generator).

In the conventional excitation system, the pilot exciter is a constant-voltage generator. The Rototrol pilot exciter is a variable-voltage pilot exciter and the method of operating the excitation system is essentially no different than the operation of conventional exciter-rheostatic systems, except in the new arrangement. no regulator-controlled, motor-operated exciter-field rheostat is used. Variable voltage is supplied to the main-exciter field by the Rototrol pilot exciter which is connected directly to the field and is under the control of the voltage regulator automatic control unit or the manual control unit.

The voltage regulator potential unit measures the positive-sequence voltage at the terminals of the generator enabling the regulator to regulate the polyphase voltages, rather than choosing the voltage of one particular phase. The voltage adjusting unit is a small hand-operated rheostat in the low-voltage circuit and is used to set the regulated voltage at the desired level at any time.

Particular attention is directed to the voltage regulator automatic control unit, which is very different from previous control units used with conventional pilot exciters. The exciter-rheostatic excitation system uses a contact-making voltage measuring unit which controls the motor-operated, main-exciter field rheostat through normal and quick raise and lower contactors. Several moving parts and contactors are used. The automatic control unit used with the Rototrol pilot exciter is a static device and completely eliminates all moving parts and all contactors. An impedance type of static network voltage regulator generally is used with generator excitation systems.

The manual control unit consists of a bridge circuit excited by the voltage drop across the main-exciter field. Again, the Rototrol control field is differentially connected in the bridge circuit. Deviation of the main-exciter shunt field voltage from its hand-set value causes an unbalance in the bridge circuit and current flows in the Rototrol control field to cor-

Paper 48-82, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 12, 1947; made available for printing December 8, 1947.

J. E. Barkle is central station engineer and C. E. Valentine is with the switchgear and control engineering division, both with the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1. Excitation system with Rototrol pilot exciter and single-field main exciter

Figure 2. Excitation system with Rototrol buck-boost pilot exciter and three-field main exciter

rect the voltage. The manual control unit, therefore, regulates the main-exciter shunt-field voltage to maintain it constant at any value set by the operator without further attention on his part.

The Rototrol pilot exciter used in this excitation system may provide either one or two stages of amplification, depending on the energy requirements of the main-exciter shunt field. The self-energized series field of the Rototrol provides all the excitation requirements of the pilot exciter when the a-c generator is operating with regulated voltage output. However, since the Rototrol operates on the linear portion of its saturation curve, the control field provides the necessary stabilizing effect and holds the Rototrol voltage at a constant value.

The Rototrol can easily be constructed to provide rates of response and ceiling voltages equal to or in excess of those obtained with conventional d-c machines. The excitation system shown in Figure 1, therefore, will provide performance characteristics at least equal to those obtained with conventional excitation systems. The series-tuned Rototrol has the advantage of utilizing the induced transient current in the generator field and in the main exciter field due to a-c short circuit or the sudden application or removal of load. The induced current flows through the self-energizing series field of the Rototrol.

The Rototrol pilot exciter, shown in Figure 1, supplies all the excitation requirements of the main exciter. In this respect, this scheme is identical with exciter-rheostatic systems using pilot exciters. The essential advantage is the elimination of the comparatively complicated exciter-rheostatic regulator with its moving parts, and elimination of the motor-operated main-exciter field rheostat. As is the case with the exciter-rheostatic excitation system, loss of the Rototrol pilot exciter through a short circuit or open circuit causes loss of excitation on the a-c generator. Past experience with pilot exciters has shown them to be very reliable. Mechanically and electrically, the Rototrol pilot exciter is as reliable as conventional pilot exciters since standard parts are used throughout in both machines except for the multiple fields in the Rototrol. The main exciter is exactly the same in either type of excitation system.

Rototrol Buck-Boost Pilot Exciter with Multiple-Field Main Exciter

The buck-boost Rototrol excitation scheme using a two- or three-field main exciter as shown in Figure 2, offers a number of advantages over the scheme just described. The voltage regulator potential unit and automatic control unit are the same as before. The Rototrol buck-boost pilot exciter is the same type of machine used in the previous scheme, but operates in a slightly different manner. Operation is best understood by analyzing the performance of the main exciter.

The main exciter is of conventional construction except that it has either two or three shunt field windings instead of the usual single shunt field. Field 1 is a self-excited shunt field providing most of the main exciter field excitation and receiving its energy from the main exciter armature circuit in the usual manner of a self-excited field. Field 3 is a small separately-excited shunt field which obtains its energy from a station battery or any other source of approximately constant d-c voltage. It is capable of supplying 5 to 10 per cent of the normal total excitation requirements of the main exciter, and its purpose is to provide exciter stability at low-voltage output under manual control. It is used only when the exciter speed of response or range of voltage output makes it desirable.

Both field 1 and field 3 have rheostats in their energizing circuits. The rheostat arms are mechanically connected together so that resistance is added in one field circuit while it is removed from the other. The combined rheostat may be either motor-operated, hand-controlled or simply hand-operated. The rheostat for the separately-excited field 3 is open circuited at approximately one-half voltage on the main exciter and remains open-circuited

Figure 3. Excitation system for hydroelectric generator with motor-driven Rototrol buck-boost pilot exciter and three-field main exciter

as the exciter voltage is further increased. Field 3 stabilizes the main exciter at low-voltage output under manual control when operation is on the air-gap line, by shifting the total saturation curve so that a positive intersection of the saturation curve with any field resistance line is obtained. Since the stabilizing effect is no longer required at the higher exciter voltage outputs, open circuiting field 3 produces no ill effects and drain on the d-c source for this field is saved.

Field 2 is a shunt field that is excited by the Rototrol buck-boost pilot exciter. In operation with this excitation system, the main-field rheostat in field 1 is set by the operator so that this field alone provides a base value of field current; for example, that sufficient to maintain steady-state stability at full load on the a-c generator. The voltage regulator then controls the Rototrol buck-boost pilot exciter output, both as to polarity and magnitude, so that the excitation provided by field 2 either adds to or subtracts from the base excitation maintaining the predetermined a-c voltage in spite of changing load on the a-c machine. The Rototrol excited field of the main exciter is in itself a stabilizing field under regulator control.

The Rototrol buck-boost pilot exciter is capable of supplying sufficient energy to the Rototrol-excited field on the main exciter so that the net excitation of the main exciter can be controlled by the voltage regulator over the normal load range of the a-c generator. A complete analysis of this excitation system shows that it offers advantages not found in the single-field main exciter scheme previously described or in conventional exciter-rheostatic systems. Since the main exciter base excitation is supplied by the self-excited field, complete excitation is not lost nor is the continuity of the load disturbed upon the occurrence of any trouble in the Rototrol buck-boost pilot exciter circuits or in any part of the static-type voltage regulator elements. Even in the event of a short circuit or open circuit in the Rototrol buck-boost pilot exciter output circuit, the preset base excitation remains rheostat controlled and undisturbed. If a circuit failure should occur at a time when the a-c generator is carrying a load other than that used to determine the rheostat setting, the a-c generator would continue to carry its kilowatt load, but at a different power factor.

Figure 5. Electronic voltage regulator schematic diagram

Rototrol Main Exciter

The Rototrol with its two stages of amplification can be built with large power output capabilities while the control field energy requirements are sufficiently small to be supplied by ordinary instrument transformers. Also, since the Rototrol is a high-speed machine with air-gap dimensions the same as any other d-c machine, it can be direct-connected to the shaft of the turbine generator. The direct-connected main-exciter Rototrol is a step toward simplification of turbine-generator construction, operation and maintenance by completely eliminating the pilot exciter. The impedance-type voltage regulator automatic control unit and the potential unit are exactly the same as those used with the Rototrol buck-boost pilot exciter. Performance of the Rototrol main exciter is comparable to that obtained with conventional excitation systems. Complete details are presented in a companion paper.[3]

Hydroelectric Generators

At present it is not practical to direct-connect the Rototrol to the water-wheel generator shaft, because of the multiplicity of speeds and sizes. The Rototrol buck-boost pilot exciter, therefore, must be driven by a small motor which introduces the problem of a reliable power supply for the driving motor. The three-field main exciter excitation system in Figure 2 is readily adaptable to slow-speed generators and is shown in Figure 3. During normal operation of the a-c generator, the excitation system will function as the three-field main exciter scheme described previously. The self-excited shunt field provides the base excitation while the Rototrol provides buck-boost action to compensate for changes in generator voltage.

Figure 4 (left). Voltage regulator static-network automatic control, potential and voltage adjusting units

Figure 6. Variable minimum-excitation control unit

During start-up of the generator when no outside source of supply is available for driving the Rototrol motor-generator set, the main exciter is operated as a self-excited machine, and will provide excitation for the main generator. As soon as a-c voltage is available, the Rototrol may be started and the voltage regulator placed in service, or operation can be continued under hand control with the operator controlling excitation with the self-excited shunt field rheostat.

During short circuits on the a-c system, the excitation system must be capable of supplying full excitation to the generator field. With the system shown in Figure 3, this is accomplished by building sufficient inertia into the Rototrol motor-generator set to carry it through such disturbances with very little change in speed even under severe forcing conditions.

An alternative answer is provided by making the Rototrol motor-generator set a three-unit set with an a-c and d-c driving motor. During normal operation the set would be driven by the a-c motor with the d-c motor floating on the station battery and acting as a d-c generator. During an a-c system disturbance the d-c machine would automatically take over the driving function, when the a-c voltage dropped. Upon restoration of the a-c voltage, the a-c motor would again drive the set.

A separate source of a-c energy, entirely independent of the a-c generator, might also be used to drive the Rototrol. Obviously such a supply must be extremely reliable unless automatic transfer schemes are provided. Any trouble on the separate a-c source, which might be a house-service generator, would disturb operation of the Rototrol excitation system causing a disturbance on the main a-c system. The most reliable system is believed to be that shown in Figure 3, where disturbance in the supply to the Rototrol driving motor occurs only when there is a disturbance on the main a-c system, and sufficient inertia in the Rototrol motor-generator set allows it to ride through the disturbance without trouble.

Synchronous Condensers

Either the single- or multiple-field main exciter Rototrol excitation system may be used with synchronous condensers. As is the case with hydroelectric generators, however, the Rototrol must be driven by a separate motor at a higher speed. Where the main exciter is separately driven as in one standard scheme now used, the Rototrol can be mounted on the main-exciter shaft as a conventional pilot exciter. The three-field main exciter is normally used with synchronous condensers because of its advantages over the single-field scheme. The main-exciter stabilizing field is necessary because of the wide range of operating voltage required of the main exciter. The single-field main exciter scheme is, however, equally applicable and, as pointed out before, comparable in performance to existing pilot exciter schemes.

Since an a-c supply must be available for starting the synchronous condenser in the usual case, the source of driving energy for the Rototrol motor-generator set is no problem. This is properly chosen as the a-c system to which the condenser is to be connected. Sufficient inertia in the motor-generator set enables it to ride through system disturbances without difficulty.

The electronic type of voltage regulator automatic control unit may be used in place of the impedance type with synchronous condensers. The electronic type functions by comparing the condenser terminal voltage with a constant reference voltage which is generated in the regulator itself. Deviation of the condenser voltage from the regulated value causes corrective action in the Rototrol control field. Standard types of electronic tubes having a high degree of reliability are used in the electronic regulator. The tubes are worked below normal rating in order to provide long life.

Figure 7. Electronic generator voltage regulator with Rototrol buck-boost exciter

Static Regulator for Rototrol Excitation System

A static-network, impedance-type, voltage-regulating equipment can be made up of a static network which includes a voltage-responsive circuit, and a self-contained reference.[4] The connections to the regulator component parts are shown in Figure 4. A-c voltage and current are connected to a voltage-regulator potential-unit which includes resistance and a filter reactor. This circuit is used to provide a positive-sequence component of voltage for the voltage responsive circuit which includes the capacitor and reactor impedance. The voltage-adjusting unit is connected between the potential unit and the voltage-regulator automatic-control unit. The voltage-adjusting unit provides a means of increasing or decreasing the resistance in series with the automatic control unit. This causes the regulator to regulate, when resistance is added in the circuit, for a higher voltage at the generator terminals: and when resistance is removed from the circuit for a lower voltage at the generator terminals.

The a-c circuit from the potential unit feeds directly the saturating reactor X, and the capacitor C circuits. The output of the reactor circuit and the output of the capacitor circuit are rectified by single-phase full-wave dry-type rectifiers. The rectifiers are then connected with additive relation in series through a resistor and smoothing reactors. The control field of the Rototrol is connected between a tap on the resistor and the opposite side of the rectifier circuit.

When the a-c voltage is normal at the point of intersection of the characteristic-impedance curves, current of equal magnitude flows in the saturating-reactor circuit and in the condenser circuit, through the resistor and smoothing reactors. Since the current in each path is the same no difference current flows in the circuit, $F1$-$F2$, of the Rototrol control field. Should the a-c voltage become low however, the current in the capacitor path is large compared to that in the reactor path.

This causes the rectifier in the capacitor circuit to put out more current than that from the reactor rectifier and

this current flows with positive polarity on *F1*, through the control field of the Rototrol. This causes the Rototrol to raise its voltage until the a-c voltage is returned to normal at which time the current flow between *F1* and *F2* approaches zero.

Should the a-c voltage become high instead of low, the current in the reactor path is large compared to the current in the capacitor path and the rectifier in the circuit of the reactor puts out more current than the capacitor rectifier and in this case the difference current is positive at *F2* flowing through the Rototrol control field. This causes the Rototrol to lower voltage until again the current in the control field circuit approaches zero.

Electronic-Type Voltage Regulator

The electronic-type voltage regulator is shown in Figure 5. This type of regulator is responsive to the average 3-phase or positive-sequence voltage by using two potential transformers and a current transformer for the average 3-phase voltage, or two potential transformers for the positive-sequence filter network. This regulator also has a self-contained reference in the form of a pentode tube. The reference voltage is produced by operating the pentode tube 1 with constant control and screen-grid voltages of the proper value. A constant plate-current characteristic is thus obtained, which is entirely independent of reasonable variations in the plate voltage. The reference voltage is obtained from the drop across resistor *R1* which carries the constant plate current. The control-grid voltage is held constant by applying the drop across the cathode resistor *R4* through which the plate current also passes. The screen-grid voltage is held at a definite value by means of the voltage-regulating tube 2. This combination provides a circuit using electronic tubes and resistors, no battery, which requires only a source of reliable a-c voltage of small capacity for the tube circuits.

The voltage-sensitive part of the circuit is a filament-controlled diode high-vacuum tube. The voltage to be controlled, either a-c or rectified from a-c, can be fed into the filament of this tube and a d-c voltage, proportional to the rms value of the a-c voltage is thus obtained from the loading resistor. This voltage is balanced against the reference voltage and the differential voltage between the two is fed into a suitable amplifier. The output of the amplifier circuit can be used to energize the control field of a Rototrol pilot exciter.

Compensation for Equalizing Loads Between A-C Machines

In each of the regulators described in the foregoing a compensating characteristic can be introduced by means of a-c machine current to cause the regulator to have a drooping or a rising characteristic with increase in reactive load.

For the impedance-type regulator a drooping or rising characteristic for the regulator voltage is obtained by means of a resistor in the regulator potential unit. By referring to Figure 4, it will be noted that potential is taken from phases 1 and 2 of the a-c machine, and current from phase 3 flows through the resistor in the potential unit. With this connection the voltage and current are in the proper vector relation so that the voltage developed in the resistor with increase in lagging reactive current can be used to provide a droop in the a-c voltage which the regulator will control. This can be used in individual regulators for a-c machines operating in parallel to make them share the reactive load. Similarly, a rising characteristic can be obtained to compensate for line drop.

With the electronic-type regulator suitable vector relation between a-c current and voltage can be secured to give a drooping or a rising characteristic to the regulated voltage.

Excitation Limits

For turbine driven a-c generators in central station service it is desirable to have the generator field excitation maintained high enough so that the a-c generator will be stable in case of system disturbance or in case of suddenly applied additional kilowatt load. The exciter voltage under regulator control should be prevented from lowering to the point of reversal.

For large synchronous condensers it is desirable to limit the a-c current with the condenser overexcited to a value within the rating of the machine. The magnitude of lagging reactive kilovolt-ampere condenser underexcited can be controlled by means of a lower limit of excitation. Circuits of the static-network type, or electronic type, are available for such control.

Figure 6 shows a minimum-excitation control circuit, the effect of which varies with kilowatt load on the a-c generator. As the kilowatt load increases a higher level of generator field excitation is required, this increase being approximately proportional to load. Connections of a-c voltage and current are made to secure the proper voltage vector relation so that the current flowing through resistor *R1* provides a voltage the magnitude of which varies with the kilowatt load. Exciter voltage is taken as an indication of generator field excitation. This voltage is applied to the d-c current winding of a saturating reactor which together with resistance and reactance in the circuit, controls the output of the rectifier and therefore the energy in Rototrol control field 2. The relation between excitation and kilowatt load may be adjusted by means of the resistors *R1* and *R2*.

The Rototrol has two control fields, one energized by the voltage regulator and the other energized by the minimum-excitation control circuit. Should the a-c system voltage rise thereby causing the regulator to lower excitation, and should this lowering of excitation call for exciter voltage below the value which has been predetermined for the kilowatt load which the a-c machine is carrying at that time, the decreasing exciter voltage lowers the saturation of the three-core reactor, thereby causing the a-c voltage to rise on the rectifier which puts current into Rototrol control field 2. This is in a direction to raise the main exciter voltage until this circuit is satisfied, opposing and overcoming, if necessary, the regulator input into Rototrol control field 1. In this way the excitation of the a-c generator is maintained with relation to the kilowatt load so as to follow a predetermined characteristic.

Similar circuits can be provided to limit the a-c current which a synchronous condenser will put out, although its automatic voltage regulator may call for increased excitation.

For an electronic-type voltage regulator circuits using tubes can be provided both for the control of exciter voltage and for limiting features. Figure 7 shows the circuits used with an electronic voltage regulator. This type of regulator controls the Rototrol by means of center-tapped field windings, one part being used for raise action and the other for lowering.

Electronic circuits for limitation of minimum exciter voltage can be added to those shown in Figure 7. The automatic voltage regulator may call for exciter voltage so low that it might permit the condenser to fall out of step. In such a case the limiting circuit provides for energizing Rototrol control field 2 if the exciter voltage drops below a predetermined point. It will then raise excitation even though the regulator may at the same time call for lowering the excitation.

An electronic circuit is also available

for limiting a-c overcurrent. This circuit is arranged to put energy into Rototrol control field 2, but in the opposite direction to the minimum exciter-voltage circuit. Should the a-c current increase above the predetermined value, current will flow in Rototrol control field 2 in the direction to lower excitation. This continues until the a-c overcurrent is reduced and the circuit is satisfied.

Conclusions

The Rototrol amplifier and its associated impedance, or electronic-type voltage regulator and limiting devices form a type of excitation system in which radical departure is made from previous excitation methods. Several advantages are gained over conventional methods with no sacrifice in reliability. Since the Rototrol is a machine of normal design, it can be direct-connected to the shaft of a turbine generator, thus maintaining the advantages of this type of drive.

When the Rototrol pilot exciter is used to energize the single field of a main exciter, it provides for automatic control by means of a regulator without moving parts and manual control by means of a small control unit, thus eliminating a large motor-operated exciter field rheostat and associated contactors. The Rototrol pilot exciter has a mechanical and electrical reliability equivalent to that of conventional pilot exciters, which have been used successfully for many years.

The Rototrol buck-boost pilot exciter and static-type voltage regulator offer advantages over other forms of excitation systems. When used with a self-excited exciter having a field energized by the Rototrol alone, the a-c machine can be operated with or without the Rototrol in service. In the latter case, the self-excited field provides excitation, being controlled manually by a main exciter field rheostat.

The buck-boost pilot exciter is also adaptable to use with hydroelectric generators and synchronous condensers. In both these cases the pilot exciter must be separately driven, which is not objectionable with synchronous condensers since a-c power must be available to run the condenser. With a waterwheel generator, the separately-driven pilot exciter may not be considered as reliable as a direct-connected pilot exciter. However, the three-field main exciter provides build-up of a-c voltage by means of its self-excited field, thus permitting starting of the station with no separate a-c supply. Sufficient inertia in the motor-driven Rototrol buck-boost pilot exciter enables it to carry through a-c system disturbances.

The Rototrol main exciter has the advantage of removing the need for a pilot exciter of any kind, and also the need for a motor-operated main exciter field rheostat. The same type of static voltage regulator as used with the Rototrol pilot exciter is employed with the Rototrol main exciter. This system is described in detail in a companion paper.[3]

Discussion

E. C. Starr (Oregon State College, Corvallis, Ore.): We are particularly pleased to see the development and practical application of excitation systems that are very fast, simple, require little maintenance and contain a minimum of moving parts. The static-type regulator with zero dead band and the rotating d-c amplifier have contributed much toward this end. With further refinements, including reduction of exciter field time constants, increase in ceiling voltages and lamination of stator structures, it should be possible and practical to so force the fields of large generators during system disturbances as to produce definite compensating changes in the "voltage behind transient reactance" during system swings having periods of 30 cycles or less. In that case transient stability would be improved and proper account of internal voltage changes should be taken in network-analyzer swing-curve studies.

We should appreciate the authors' comments on the possible extent and timing of this voltage change such as might be produced practically in large synchronous generators and condensers.

J. E. Barkle and C. E. Valentine: In reply to the discussion by E. C. Starr. The authors wish to state that they are also much interested in the possibilities along the lines suggested by him. The best answer so far as forcing the field of the large ac machine is concerned, lies in the use of an all-electronic excitation system. Next to this is the use of a rotating amplifier-type main exciter, designed to have a high rate of response.

A main exciter of conventional construction and a buck-boost rotating amplifier have inherently less fast response over-all, than a main exciter Rototrol. To comment more completely and accurately, as suggested, taking into account the many variables involved would require considerable time and study. Undoubtedly, improvements over past performance can be made as experience with the new excitation systems increases.

Main Exciter Rototrol Excitation For Turbine Generators

C. LYNN
MEMBER AIEE

C. E. VALENTINE
MEMBER AIEE

WITH the increase in size of turbine generator units and the accompanying higher steam pressures and higher temperatures, these generating equipments have become more of the unit type. Boilers, power house auxiliaries, turbines, generators, exciters and regulators function as a unit for an individual equipment. Owing to the more efficient operation of these units, it is desirable to keep them continually on the line. Shutdown periods that previously were considered normal for boiler and station auxiliaries, which in the past provided time for brush replacement and other usual maintenance operations on exciters, are no longer permitted, as these equipments are now designed to operate over very much longer periods between shutdowns. Excitation systems, therefore, have also been redesigned from the standpoint of continuity of operation.

The use of Rototrol pilot exciters, direct connected for new installations, and separately motor driven for older installations, where direct-connected units cannot be installed, using static networks for voltage regulation, has eliminated sources of possible shutdowns and at the same time has improved the over-all excitation operation. A companion paper[1] covers Rototrol excitation systems, in general, and mentions main exciter Rototrols for turbine generators.

The surest way to eliminate failure of any piece of apparatus is to either eliminate the apparatus or modify it to make it simpler, so that there is inherently less chance of failure. In main exciter Rototrol excitation for turbine generators, not only is the regulator with contacts and contactors eliminated, but also the pilot exciter. In this type of equipment, therefore, we accomplish with one main exciter, complete excitation, stability and regulation in the one unit, with only the addition of a static voltage regulating network. The latter being static has, of course, no moving parts. Our purpose is accomplished in this one exciter without the use of any additional brushes, short circuited windings or connections, or other constructions that are critical in adjustment or have additional potential possibilities of trouble. Since the amplification is produced in the main exciter itself, it is built as a two-stage rotating amplifier instead of a single-stage unit, in order to require only a nominal amount of control energy from the static network. The principle and operation of the two-stage Rototrol has already been covered in the AIEE papers.[2,3] Rototrols of the two-stage type previous to this application for turbo-exciter excitation, have been built in capacities up to 15 kw at 1,200 rpm.

Main Exciter Rototrol

The 200-kw 250-volt 3,600-rpm main exciter Rototrol, is shown on the test floor in Figure 1, with cover removed, built for a large western utility company, for the excitation of a 60,000-kw 13,800-volt 85 per cent power factor, 3-phase 60-cycle 3,600-rpm turbogenerator. This is the first unit of this type to be built, and it will be necessary to gain field experience before additional machines are made generally available.

Figure 2 shows the unit with cover in place. In general, the unit follows the latest type of Westinghouse direct-connected turbo exciter construction with "rollaway" type of cover. This gives an enclosed machine for normal operation, having far greater accessibility for brush replacement and inspection, with the cover removed, than any open-type d-c machine of similar size built heretofore.

Figure 3 is a close-up of the current collecting parts, and Figure 4 shows the brush holder. This is a double-type brush holder, providing brush replacement using standard shunted brushes, without the use of any tools around the machine, while the machine is in normal operation. Shutdowns, therefore, are not necessary for brush replacement. The brushes are normal in number and arrangement, the same as on a conventional type 200-kw 3,600-rpm exciter. A depressed type of bedplate is used, giving a large open space underneath the commutator for ease of brush replacement. No structural members other than the brush holder rods lie in the space surrounding the commutator. Shrink rings are used on account of the high speed involved and the shrink ring commutator is the Westinghouse floating type with means provided to take care of radial and axial expansion caused by temperature changes and stresses of the rotation. The armature winding is of the conventional lap type with cross connections omitted. The openings between the commutator necks are filled with insulating material and the armature winding is packed behind the necks and under the front coil extensions to eliminate creepage paths which might cause low insulation resistance due to flyash in the air. The only exposed live-creeping surfaces on the armature are the insulation adjacent to the shrink rings and the insulation adjacent to the bands on the front armature coil extensions, both of which can be cleaned with compressed air, with the unit in operation, or wiped by hand under slow roll condition, if found necessary.

The stator is of normal design, with the exception of modified brush holder cross

Paper 48-83, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 12, 1947; made available for printing December 5, 1947.

C. LYNN is with the direct current engineering department, and C. E. VALENTINE is with the regulator section, switchgear engineering department, of the Westinghouse Electric Corporation, East Pittsburgh, Pa.

Figure 1. Main exciter Rototrol, 200-kw 250-volt 3,600-rpm. Set up for factory test

Figure 2. Main exciter Rototrol, 200-kw 250-volt 3,600-rpm. With enclosing cover in place

connections and additional windings on the fields as required to obtain two stages of amplification in one unit. In order to minimize the effects of hysteresis, materially eliminate eddy current effects and provide faster speed of response, a laminated type frame is used, providing a completely laminated structure for the main field flux. The commutating pole windings and the series field windings, as well as the shunt field windings are also insulated throughout the full length to eliminate creepage paths. Pedestal-type bearings are used since these require no tying members to the frame and permit maximum accessibility, particularly in regard to oil seals around the shaft, thus minimizing the possibility of oil leakage.

The exciter is driven from the commutator end by a fast flexible coupling connecting it to a stub shaft on the end of the a-c generator. A double type fan is mounted on the end of the turbine generator shaft and provides separate ventilation systems for the a-c exciter and the a-c generator collector rings. Baffles or bulkheads, built into the machine and projecting inwardly from the cover, with rubber seals provide partitions in the exciter housing for directing the ventilating air in the paths for most efficient cooling. The ventilating air flow is from the rear of the machine towards the commutator and fan, so that no carbon dust from worn brushes can be drawn into the machine windings. An end bell at the rear edge of the frame directs the air into the rotor and field coils in the correct proportions. The baffle at the front end of the commutator causes the ventilating air to pass over the commutator, thus cooling it and the brushes before passing into the fan. Air for ventilating the collector rings is carried from the rear of the exciter in hollow tubes through the base, to the a-c generator field collector rings and brushes. The fan blades on the collector side of the exciter fan provide air circulation in the collector ring compartment. Suitable filters are used at the air entrance into the exciter unit. The air discharge is directly below the fan, located at the end of the a-c generator shaft. Suitable inspection openings are provided in the cover, with interior lights provided for illumination, so that operation can be observed with the cover in place. The cover is not attached to the exciter but is mounted on rollers which are brought into play by movement of a handle at the end of the cover. When this handle is pulled rollers are depressed so that the complete cover can be rolled away from the exciter, uncovering successively the a-c collector rings and brushes, and the commutator and its brushes. This can, of course, be done with the unit in normal operation. This requires a cover movement of less than half of its length. As a turbine generator exciter, the design is made for maximum accessibility and continuity of service.

Regulation of Voltage

The regulation of the terminal voltage of the Rototrol main exciter and of the a-c machine which it excites, requires a voltage-responsive device or circuit which can transmit the proper intelligence to the control field of the Rototrol. The multistage Rototrol exciter or d-c generator differs from the conventional d-c generator or exciter in the magnitude of its amplification. Since it is designed with the object of providing maximum amplification in output terminal voltage for a small change in the control field input energy, it becomes possible to control this type of machine with a small amount of energy from a voltage-responsive regulating device or circuit.

Any one of a number of regulating devices or circuits can be used. Electromechanical devices, in general, have the advantage of having a convenient fixed reference such as the tension of a coiled spring, but have had, until within recent years, the disadvantage of moving and wearing parts. Direct-acting rheostatic type regulators which use complete spring mounting for the moving parts[4] have overcome essentially the disadvantages of these wearing parts. This direct-acting type of regulator can be used to control the Rototrol by putting the control field in a Wheatstone-bridge circuit.

Regulating action, similar to that obtained with electromechanical devices, can, however, be secured by means of static circuits with or without electronic tubes. Electronic-tube circuits can be made extremely sensitive, can have high amplification, and with suitable power source can provide relatively large output energy for a very small amount of input intelligence. Electronic tube circuits have many interesting possibilities for voltage-responsive and other regulating

Figure 3. Close-up view of type of current collecting parts used on 200-kw 250-volt 3,600-rpm main exciter Rototrol

Figure 4. Brush holder used on main exciter Rototrol permitting brush replacement without tools

functions. Electronic input or measuring circuits have the advantage in general of requiring a small amount of energy from potential or current transformers on account of the sensitivity and amplification within the tube or tubes. A basic requirement for this type of circuit, however, is a reliable source of energy for the amplifier and rectifier tubes. Electronic tubes require some attention over a period of months or years of operation, to check operating characteristics and to replace when necessary.

The static network circuit[4] without electronic tubes can be made up of component parts which do not require replacement. These parts include transformers, reactors, condensers, resistors, and dry-type rectifiers. The input energy for this type of circuit is in general higher than for electronic circuits, and may be supplemented by separate-source energy. Network circuits of this kind were developed and used for various purposes during World War II. Further development of such circuits has continued since the war.

In the voltage-responsive static circuit, a self-contained reference is desirable, although a separate source of energy such as a battery or constant-potential device may be used. This reference takes the place of the spring in the electro-mechanical type regulator. For this purpose the voltage and current characteristics of differing types of impedance may be employed. The circuit described in this paper uses a reference which consists of the intersection of a non-linear impedance characteristic obtained from a reactor, and a linear impedance characteristic obtained from a condenser. The voltage-responsive regulating circuit is satisfied or "balanced" at the point of intersection of the impedance characteristics. Any deviation from the level of voltage for which the intersection is designed will result in a current difference in the static network circuits which is used to provide energy of a given polarity or of the opposite polarity to energize the Rototrol control field.

Figure 5 illustrates the intersecting impedance characteristics. The curve *OPX*, a nonlinear curve, shows the relation of a-c applied voltage E and the current I flowing through the saturated reactor. The curve *OPC*, a straight-line curve, shows the relation between the applied a-c voltage E and the current I through the capacitor. The value of voltage chosen for the intersection of the impedance characteristics corresponds to a value somewhat less than the normal voltage of the a-c generator, reduced through potential transformers. A suitable range of adjustment for the level of voltage which the generator will hold is obtained by means of variable resistance connected in series with the circuit which gives the fixed reference level. The switchboard operator turns his voltage-level adjusting rheostat, thereby varying the resistance in the circuit, to adjust the level of voltage which it is desired that the regulator shall hold.

An excitation system with the static regulator network, is shown in Figure 6. The voltage regulator automatic control unit includes the saturating reactor and capacitor circuit. Other component parts are the voltage regulator potential unit and the voltage adjusting unit. In the potential unit, a-c potential and current are used to provide positive-sequence voltage for the automatic control unit, and adjustment for equalizing the reactive load between a-c machines which operate in parallel. A regulator control switch is used to cut the regulator into or out of service. A manual control unit is provided to control the Rototrol exciter manually when the voltage regulator is not in service.

Figure 7 shows the internal connections for the automatic control unit and for the potential unit. For the automatic control unit this shows the input a-c voltage, feeding direct to the capacitor circuit C, and to the reactor circuit X. These circuits each energize a dry-type rectifier. The output of the rectifiers is connected in a series additive relation through a suitable tapped resistor. The Rototrol control field is connected from the center of the resistor to the opposite side of the rectifier energized circuit.

When the intersecting impedance circuit is satisfied with voltage at the intersection of its electrical characteristics, the current and voltage output of each rectifier is the same. No difference current appears in the Rototrol control field. Should the a-c voltage drop below normal, the current in the reactor circuit becomes less than that in the capacitor circuit thus causing a current to flow in the Rototrol control field with the polarity of the capacitor rectifier. The flow of the current is in the raise direction to cause the Rototrol to increase its output, thus restoring the a-c generator voltage to normal.

Should the a-c voltage rise above normal it will be noted that the current in the reactor circuit becomes greater than that in the capacitor circuit, this resulting in a difference current in the output of the rectifiers, the polarity being that of the rectifier in the reactor circuit. This

Figure 5. Static impedance type voltage regulator—linear and nonlinear impedance characteristics

Figure 6. Excitation system with Rototrol main exciter and impedance type voltage regulator

Figure 9. Comparison of voltage dip and recovery time main exciter Rototrol regulating system and conventional main and pilot exciter with contact-making regulator

polarity is opposite to that resulting when the a-c voltage is low, and the Rototrol control field is thus energized in the lower direction to decrease its output voltage and that of the a-c generator to return the a-c voltage to the normal value.

The manual control unit includes a bridge circuit and rheostat which is energized from the output of the Rototrol. The circuit includes resistance and a dry-type rectifier arranged for connection to the control field as shown in Figure 8. For a given setting of the manually operated rheostat, the circuit is self-regulating to control the Rototrol output voltage, maintaining it at a predetermined value. Turning the rheostat to a new position raises or lowers the Rototrol output voltage as required, and thereby controls the generator a-c terminal voltage.

The regulator control switch is used to change from manual to regulator control and vice versa. This switch has four positions; manual, regulator test, manual test and regulator. When changing from manual to regulator control, the switch is turned to the regulator test position and the automatic control unit output is adjusted by means of the voltage adjusting unit and voltmeter to match that of the manual control unit. The switch is then turned to the regulating position and the regulator takes control of the a-c voltage. When changing from regulator to manual control, the switch is turned to the manual test position and the manual unit output is adjusted by means of its rheostat and voltmeter to match that of automatic control unit. The switch is then turned to the manual position. When the manual control unit is being used, should the exciter voltage start to change from the setting determined by the position of the manual control rheostat, the bridge circuit in this unit energizes the Rototrol control field in the proper direction to return the Rototrol exciter voltage to the predetermined manual setting.

Figure 8. Manual control unit—schematic diagram

The large main exciter Rototrol has been tested and shipped, and the unit is now being installed. The following factory tests were obtained with the exciter and its static voltage regulation network, loading the unit on the fields of a large a-c generator comparable in characteristics to that of the generator which it will excite. Companion tests were made on a similar size unit of conventional construction, using a main exciter, a pilot exciter, and a modern exciter rheostatic-type voltage regulator.

Factory Tests

The a-c generator was a 20,000-kva 6,600-volt 3-phase 60-cycle 600-rpm laboratory test machine. The excitation requirements and time constant of this generator are comparable to those of the 70,500-kva 3,600-rpm turbine generator which will be excited by this main exciter Rototrol. The 250-volt 3,600-rpm main exciter Rototrol was connected to energize directly the field windings of this generator. A 3-phase reactor load was suddenly applied, causing about 20 per cent rated a-c generator amperes to flow in the load circuit. Figure 9 shows the voltage dip and recovery as plotted from an oscillogram. This voltage dip was $5^1/_2$ per cent, and was followed by a return to normal voltage in 23 cycles, and final recovery in about two seconds. It should be noted that the static-network regulator and machine adjustments in general, which provide for recovery in the shortest possible time are accompanied by a greater overswing and underswing of the regulated voltage, compared to the use of a slower rate of recovery. With a slower rate of recovery, the swinging of the voltage above and below the regulated value can be decreased. The available test facilities did not permit applying loads of greater magnitude. The test as made, however, indicates relatively rapid response of the Rototrol voltage, with the required forcing ability to return the a-c generator voltage to normal in spite of relatively long time delay inherent in the a-c generator field circuit.

The dashed curve in Figure 9 shows typical performance of an exciter rheostatic voltage regulating system, using conventional 250-volt 3,600-rpm main and pilot exciters. For this test a 250-volt 3,600-rpm conventional type main exciter, with a directly connected conventional pilot exciter, was connected to energize directly the field windings of this same laboratory a-c generator with the shunt field winding of the main exciter energized from the constant voltage of the pilot exciter. A motor-operated rheostat and suitable blocks of field-forcing-up and field-forcing-down resistance were connected in series with the fields of the main exciter. In this test the reactor load was slightly greater in magnitude than that used for the main exciter Rototrol tests, and was suddenly applied in the same manner. The dashed curve shows an

initial voltage dip of 7 per cent and a recovery time of three seconds.

With this type of regulator it should be noted that the rate of recovery of the a-c voltage depends on the contact gap and timing adjustment which is used with the high speed contactor, and also upon the speed of the motor-operated rheostat. The dashed curve of Figure 9 shows an adjustment of the regulator contacts which energize the high speed contactors of plus or minus $2^1/_2$ per cent. The normal-response contacts which control the motor-operated rheostat, were set at plus or minus one-half of 1 per cent.

The voltage dip of the recovery of the exciter rheostatic regulator can be improved by setting the contacts which control the high-speed contactors to a small percentage value. The practice of different operating companies varies considerably in this respect. Where the generator load is likely to fluctuate widely or violently, the contact gap setting for the regulator quick-response contacts may be only a little greater than that of the normal-response contacts. For the majority of public utility system regulators, however, the setting of the quick-response contacts is usually greater, for example, between plus or minus 3 and plus or minus 5 per cent. With this setting the high speed contactors operate very infrequently, providing mainly for voltage regulator high speed action, which takes place only in case of serious a-c system disturbances. For the usual system load changes the normal-response contacts regulate the a-c voltage by controlling the motor-operated rheostat alone.

The main exciter Rototrol has the advantage of combining in one rotating machine the amplification necessary for control directly by the voltage regulator and ample power output for connection directly to the field of the turbine driven generator. Since the Rototrol is series tuned it utilizes the inherent transient characteristic of the a-c generator field wherein current increases or decreases momentarily under the condition of sudden application or removal, respectively, of load. This amounts to an anticipatory action as far as the regulator is concerned because the Rototrol starts to change its output prior to action by the regulator in the Rototrol control field circuit.

The voltage regulating system described has the advantage of a regulator without moving parts, without contactors, and requiring no large motor-operated main-exciter field rheostat. The over-all performance of the regulator, Rototrol exciter and the a-c machine, shows marked improvement in voltage dip and recovery time. The quicker recovery of the a-c voltage and even some over-swing, is in a direction to greatly improve stability during the transient period. Such a system also eliminates the use of a pilot exciter without effecting the stability of the main exciter. The Rototrol main exciter is connected to and driven by the turbine generator, and is controlled directly by the regulating equipment, simplifying the regulating and excitation system.

Discussion

Alexander Dovjikov (Bonneville Power Administration, Portland, Ore.): As the control field provides only the necessary stabilizing effect, holding the rototrol voltage at a constant value, and all the excitation requirements of the pilot exciter are provided by the self-energized "series" field, we see in this development a feature in which we have been interested for a long time, a feature which European designers took advantage of long ago by using and advocating further use of series exciters.[1,2] The reason for a series winding, as recognized by Barkle and Valentine, is that the series-tuned rototrol has the advantage of utilizing the induced transient current in the generator field and in the main exciter series field winding due to a-c short circuit or the sudden application or removal of load. We were very interested to see that the machine not only has a shunt winding but a series winding as well, and that

"the laminated type frame is used, providing a completely laminated structure for the main field flux."

It should be emphasized that for the fastest response the magnetic circuit of the machine must be laminated, and we are glad to see this principle incorporated in the design of this exciter.

We are also very interested in Figure 9 of the paper representing the voltage-time curve of a Rototrol regulating system with approximately 20 per cent of rated current at low power factor suddenly applied. With this type of load applied, it naturally takes time to build a quite considerable additional air-gap flux required by the load, and the indicated speed is fairly promising for application when fast increase in internal electromotive force is desired, as for example, during swings. From a stability point of view, we would like to see the same kind of graph (with space 0–30 cycles considerably expanded and with more details) for a typical large generator with excitation corresponding to the full load, the fault applied and then removed in approximately three to five cycles, the conditions at which it is desirable not only to maintain the air-gap flux, but even to increase it during the subsequent swing of the synchronous machines.

Frank V. Smith (Sargent and Lundy, Chicago, Ill.): The authors have presented a paper of considerable interest. The prospect of eliminating the pilot exciter on large turbine generators is one that will be welcomed by power engineers. This small machine on the end of the shaft has been a matter of concern to operators who fear the outage of much needed capacity because of trouble with the pilot exciter. Its existence has been a factor in the use of separately driven exciters in some cases although this solution is not altogether satisfactory because of the added complications of motor and control and the requirements of high inertia to hold the exciter voltage up during a-c disturbances. The main exciter Rototrol described here has yet to be proven in service. Applications of the static regulator and the Rototrol to replace the pilot exciter have been made only recently and very few of these are yet in operation. Power engineers will look forward to the record of experience in the field.

The Effect of Coulomb Friction on the Performance of Servomechanisms

G. D. McCANN
MEMBER AIEE

F. C. LINDVALL
FELLOW AIEE

C. H. WILTS
NONMEMBER AIEE

THE EFFECT of coulomb friction on the performance of three basic types of speed-regulating and position-regulating systems has been studied by means of the electric analog computer. The analysis presented here shows the effect of such friction forces on servo performance including speed of response, damping, and control error. The amount of coulomb friction is specified in terms of a dimensionless parameter called "the friction ratio" that relates the friction force or torque to the disturbance. The equation for the friction ratio varies with the type of system and disturbance and must be specifically defined in each case.

It was found that the presence of coulomb friction in the follow-up motion portion of a position-follow servo always increases damping, but also increases the error and decreases the speed of response. However, if the coulomb friction is present in a portion of a servomechanism containing a degree of freedom different from that to be specifically regulated, its effect is usually one of destabilization. In the case of a simple speed governor described by a cubic equation, coulomb friction in the governor mechanism will cause destabilization and poor performance in governors otherwise made stable by appreciable viscous damping. However, in a limited region of system parameters characterized by low viscous damping in the governor, it can increase stability. Appreciable coulomb friction in the control surface circuit of the auto pilot selected for study was found to be undesirable in the practical range of the system parameters. Damping of an otherwise unstable auto pilot can be achieved with coulomb friction but poor over-all performance is indicated. Under certain conditions the destabilizing effect of coulomb friction can be overcome by increased damping from both the air frame position and the control surface position.

The variable effects of coulomb friction and the conditions under which these effects become appreciable are discussed.

Although coulomb friction is frequently found to be an important factor in self-regulating systems, its general effects on servo performance have not been adequately analyzed. Its discontinuous nature prevents detailed study by conventional mathematics. However, it is a relatively simple function to represent by electrical analogy, and the electric analog computer is well adapted to a complete study of its effects. The California Institute of Technology computer[1] has now been used for a general exploratory analysis of the effect of coulomb friction in three basic types of servomechanisms: position follow-up servos, speed governors and auto pilots.

Electrical Analogy for Coulomb Friction

Coulomb friction is defined as a constant force or torque, independent of velocity, that always opposes motion. When the sum of all other forces on an object is less than the friction force, grabbing occurs. These conditions are satisfied by the circuit of Figure 1, when the force-voltage analogy is used. Examination of this circuit shows that if the back impedance of the rectifiers is assumed to be infinite, current cannot flow through either branch of the circuit until a voltage opposite to and greater than the respective battery voltage is reached. In the electrical analog this current is analogous to velocity. Thus when the voltage exceeds the coulomb friction voltage E_f, the system can move but the friction voltage is inserted in such a manner as to oppose the motion.

Figure 1. Electric analog for coulomb friction

Batteries with internal impedance sufficiently low to be negligible are easily obtained. It is, however, necessary to consider the forward resistance of the rectifiers and the ratio of forward to back impedance. Dry-type rectifiers or "Germanium" crystals with forward resistances of about 50 ohms and back impedances of 200,000 ohms were used for part of the solutions presented here. For other solutions vacuum tube diodes were used because it was desired to have as part of the analogy a relatively small capacitor in series with the coulomb friction circuit, thereby requiring a much higher back impedance in the rectifiers. Thus, during the period when the system is stopped by the friction force, the discharge rate of the capacitor is truly negligible. For all cases circuit parameters were chosen such that the forward resistance of the rectifiers was only part of the total resistance representing the viscous damping in the physical system.

Basic Systems Studied

The three basic types of system studied are illustrated in Figures 2, 3, and 4, together with their characteristic equations and their electric analogies.

Paper 48-84, recommended by the AIEE joint subcommittee on servomechanisms and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 24, 1947; made available for printing December 30, 1947.

Figure 2. Basic examples of coulomb friction forces in simple systems expressed by quadratic equations $p \equiv d/(dt)$

Figure 3. Basic speed governor with coulomb friction in the control system

Simple Systems Represented by Quadratic Equation

Jacobsen[2] and Den Hartog[3] have made a detailed analysis of coulomb friction in a single degree of freedom system, as illustrated in Figure 2*a*, under the action of a steady sinusoidal force. As a starting point, therefore, the results of these earlier analyses were checked with the computer. Also, the action of such a system under suddenly applied constant forces was studied in detail with the computer. Figure 2*b* represents a simple position follow-up type of servo specified by the same form of quadratic equation when only simple error control is employed and all time delays are neglected. Appreciable coulomb friction can be present in the portion of such a system containing follow-up motion θ. The analogous circuit of Figure 2*c* is, therefore, suitable for both physical systems being considered here. Such an analogy has the advantage that low viscous damping can be simulated even though relatively high linear resistance is present in the coulomb friction analog.

In the analogy of Figure 2*c*, the application of a sudden force on the system of Figure 2*a* was simulated by insertion of a voltage in series with E_f. Sinusoidal forces were simulated by sinusoidal current forced into the circuit by the generator G. This same forcing function also simulated the action of the position servo of Figure 2*b* when trying to follow a sinusoidal motion. The follow-up type of servo was studied under the action of suddenly applied constant velocity motion ($\theta_a = v_a t$) by introducing into the analogous circuit the constant current i_a. This class of servo was also studied with two time delays and anticipation feedback.[4]

Solutions in the analog of Figure 2*c* were recorded as follows. For suddenly applied forces in the system of Figure 2*a*, the voltage across the capacitor C_a was recorded since it is proportional to the charge q, which, in turn, is analogous to displacement x. For all other cases in which the current i_a was introduced into the circuit, the voltage across C_a gives the error motion $q_a - q$, which is analogous to $\theta_a - \theta$. To measure the total motion θ of the system, a very large capacitor was inserted in the RL series circuit.

Simple Speed Governor Represented by a Cubic Equation

This basic system is shown in Figure 3 with the electrical analogy that was set up on the computer. This type of governor without coulomb friction is treated in reference 5. As an illustration, a simple flyball governor directly operating a control valve through linear motion is shown in Figure 3, although the characteristic equation studied is of more general application. Here coulomb friction is assumed to be present only in the control system, as it would not be appreciable in the actual machine whose speed is to be controlled. The analysis was made for fixed load torque increments suddenly applied. This condition is simulated in the analogous circuit of Figure 3*b* by the suddenly applied constant voltage E, as shown. The transient speed drop ω is recorded by measuring the voltage across the resistor R_1. The motion x of the control system is proportional to the voltage across the capacitor C_2.

Auto Pilots

The basic system selected for studying auto pilots is shown in Figure 4. Motion in only one axis of the air frame was assumed and interactions between other degrees of freedom were neglected. The transfer equation of the air frame was represented by inertia I and aerodynamic damping c. Any air frame restoring moment was neglected. The control system was assumed to have inertia and a hinge moment spring constant together with both viscous damping and coulomb friction. This system was first studied with feed-back control from the air frame position angle alone. Such servos usually require feedback from the control surface motion and these studies showed this factor to be even more important with large amounts of static friction present. Therefore, the system was also studied with feedback from rudder angle, as illustrated

in Figure 4*a*. In the electrical analogy of Figure 4*b* the voltage across C_a is proportional to the air frame angle θ and the voltage across the capacitor C_1 is proportional to the control surface angle δ. This system was studied under the action of constant torques suddenly applied to the air frame. The suddenly applied constant voltage E in the analogy simulated the disturbing torque.

Effect of Coulomb Friction in Systems Described by Quadratic Equation

As indicated in Figures 2, 3, and 4, the amount of coulomb friction for each case to be considered is specified in terms of a friction ratio whose definition varies with the respective systems. This friction ratio is specifically defined for each set of solutions presented.

Sinusoidal Motion

As mentioned previously, Den Hartog[3] presents a general analysis of a simple mechanical system with one degree of freedom under the influence of a sinusoidal applied force. His analysis is presented in the form of curves showing amplitude and phase angle of the system motion as a function of viscous damping, ratio of applied force frequency to system natural frequency, and ratio of friction force to applied force. These curves were spot checked with good agreement. Den Hartog found a region where the motion of the system departs considerably from that of a sine wave. This occurs for high ratios of friction force to applied force and low ratios of applied force frequency to system frequency. A typical solution in this region as recorded in this paper is shown in Figure 5. This particular solution is illustrative both of the physical system of Figure 2*a* and the servomechanism of Figure 2*b*. With high friction ratios, the system can grab and be held still for appreciable periods of time. At each instant when the force in the system again exceeds the friction force, a transient condition is initiated causing the system to oscillate at its natural frequency. Under certain conditions these free oscillations can reduce the total system force sufficiently to cause successive grabbing or chattering at the high frequency rate. In the situation of Figure 5, the friction ratio is not sufficiently high for this high frequency chattering, and the system is grabbing only on the peak of each swing, the oscillation corresponding in frequency to that of the motion to be followed, or the applied force. As the system breaks away a transient oscillation is initiated. This effect is seen more clearly in the solution of Figure 5 for the error angle because of the higher amplification factor used for that record. With a substantial increase in viscous damping in the system, these transient oscillations can be damped out and the high frequency chattering eliminated.

Response to Suddenly Applied Forces

In Figure 6 typical solutions are given for the system of Figure 2*a* under the influence of a suddenly applied force. In this figure the fraction of critical viscous damping r is 0.01. Solutions were also obtained for values of r equal to 0.1, 0.25, 0.50, and 1.0. As would be expected, the presence of coulomb friction in the same part of a system to which a disturbance is applied, increases the system damping.

Figure 4. (left). Auto pilot with coulomb friction in the control surface mechanism

Figure 5. Typical solution to simple angle-position servomechanism following sinusoidal motion when friction ratio $T_f/(K\theta_{max})$ is high and ratio of forcing function frequency to natural frequency is low. $\omega/(\omega_n) = 0.1$, $r = c/(2\sqrt{KI}) = 0.01$

This observation might lead to the erroneous conclusion that coulomb friction in any part of a servomechanism increases system damping. For the single degree of freedom case, coulomb friction without viscous damping causes the system oscillations to decay in the form of an arithmetic progression[8] without change in oscillation frequency. This effect can be seen in Figure 6. As the friction ratio is increased, the system oscillations are snubbed more and more quickly until for a certain value of friction ratio there is no overshoot. For $r=0.01$ this condition occurs at a friction ratio of about 0.50 (see Figure 6); for larger values of r this occurs at lower and lower values of friction ratio. (For $r=0.25$ at friction ratio $=0.30$ and for $r=0.5$ at friction ratio $=0.12$.) However, up to this point the steady-state value of the solution is not appreciably affected by the presence of coulomb friction. For higher friction ratios the steady-state error is $F-F_f/(K)$ since no overshoot is permitted.

The Effect of Coulomb Friction in Speed Governor

The solutions of Figure 8 provide a composite picture of the various effects of coulomb friction as the basic parameters of the speed governor described in Figure 3 are changed. This servo may be described by three basic dimensionless parameters. The first of these, $mG_1G_2/(kIc)$, describes the amount of damping in the linear system without coulomb friction. When equal to one, the system has zero damping. This factor is varied from 0.2 to 2.0 in the solutions of Figure 8. The second parameter, $c/(2\sqrt{mk})$, specifies the amount of viscous damping in the governor alone. Its effect was studied over a range of 0.05 to 3.0 of critical. The third factor, $\frac{G_1}{c}\sqrt{\frac{m}{I}}$ provides the additional parameter required to specify the system, exclusive of the actual time-base or system frequency.

Examination of Figure 8 shows two definite regions in which coulomb friction has diametrically opposite effects. In regions where the per cent of critical damping of the governor system alone is low or the factor $mG_1G_2/(kIc)$ is high so that the system without coulomb friction has little damping, the addition of coulomb friction has a beneficial effect by increasing the damping. This beneficial effect is greatest for low values of viscous damping in the governor system. With $c/(2\sqrt{mk})$ equal to 0.1 or less, very large amounts of coulomb friction can be tolerated and the system thereby damped.

However, an increase in the friction ratio above certain limits results in a decrease in the system response rate and an increase in the steady-state speed drop. It therefore appears practical to rely on coulomb friction under certain conditions for system damping if a maximum value of the disturbance torque can be fixed so that the friction ratio will not drop below the critical value necessary for adequate damping. This critical value of the friction factor was found to vary directly with the third dimensionless parameter, $\frac{G_1}{c}\sqrt{\frac{m}{I}}$.

As an example of this effect, it was found that for $c/(2\sqrt{mk})=0.1$, very satisfactory system performance could be obtained with $mG_1G_2/(kIc)$ as high as 2.0 for a friction ratio as low as 0.07 when $\frac{G_1}{c}\sqrt{\frac{m}{I}}=0.25$. As this last factor is increased the minimum permissible friction ratio must increase proportionally. With less viscous damping, $c/(2\sqrt{mk})=0.05$, good performance can be obtained with $mG_1G_2/(kIc)$ as high as 3.0, with a corresponding lower limit of 0.08 for the friction ratio if $\frac{G_1}{c}\sqrt{\frac{m}{I}}=0.40$. Reduction of this last factor allows a decrease in the friction ratio. As the viscous damping in the governor system is increased, the region in which coulomb friction has a stabilizing effect narrows rapidly and the relative amount of damping it can produce in this stabilizing range decreases.

In the region of sufficiently high viscous damping in the governor system to provide a well-damped solution, the solutions of Figure 8 show that coulomb friction is

Figure 6. Solutions to system of Figure 2a under action of suddenly applied constant force. $r=c/(2\sqrt{KI})=0.01$. Friction ratio $=F_f/(F)$

Figure 7. Solutions to basic position follow-up servomechanism of Figure 2b for suddenly applied constant velocity (V_o). Friction ratio $=T_{f_{MR}}/(KV_o)$, $(\theta_o-\theta)_{ss}=cV_o+T_f/(K)$

Figure 8. Solutions to speed governor of Figure 3 under action of suddenly applied load torque. Characteristic equation is expressed in dimensionless form by the parameters: $mG_1G_2/(kIc)$, $c/(2\sqrt{mk})$, $G_1/c\sqrt{m/I}$. Friction ratio $= G_3F_1/(kM)$

definitely harmful in that it decreases the damping of the speed drop curve and as this friction becomes larger, it causes increased amplitude of oscillation. Where appreciable coulomb friction is present, the frequency of oscillation of both the governor and the controlled system decreases with time. The governor moves in a jerky motion as it is stopped by the coulomb friction at successive intervals. The period in which the control system is at rest increases progressively as the magnitude of motion decreases and the speed fluctuates at correspondingly slower rate. It would appear that under these conditions the system would probably never reach a truly stable condition, but would hunt indefinitely with very low or negligible magnitude. (The magnitude of this hunting would under most conditions probably be unimportant.)

Thus, it is apparent that coulomb friction is detrimental in systems designed for good performance on the assumption of a linear behavior alone. The linear solutions obtained for this system show that without coulomb friction, good system performance can be obtained with the factor $c/(2\sqrt{mk})$ ranging from about 0.3 to 0.8 and $mG_1G_2/(kIc)$ lying between about 0.25 and 0.65. The use of greater viscous damping results in decreased speed of response. As the viscous damping is lowered below this range the required low values of $mG_1G_2/(kIc)$ prevents close regulation.

The general effect of coulomb friction as previously described on speed governors had been found experimentally[7] and has led to the conclusion by some that simple speed governors should be designed with low viscous damping and appreciable coulomb damping. This, however, has the disadvantage that performance is defi-

A—Effect of coulomb friction when system is otherwise undamped

B—Case where coulomb friction stabilizes control surface but destabilizes air frame

Figure 9. Typical solutions to auto pilot of Figure 4. Characteristic equation expressed in dimensionless form by the parameters: $a = T_a/(T_e)$, $b = c_1/(K_1T_e)$, $d = I_1/(K_1T_e^2)$, $e = Gk_1k_2/(K_1cT_e)$ and k_3 where $T_e = 1/(c)$. Friction ratio $= M_1G/(K_1M)$

nitely dependent upon the magnitude of the disturbance torque on the system. Better performance can be obtained through the elimination of coulomb friction in favor of stabilization either by viscous damping alone, or by feedback around the governor system itself. With either type of stabilization coulomb friction is unnecessary and generally harmful.

Effect of Coulomb Friction in Auto Pilot

For a general analysis of the auto pilot system described in Figure 4, use was made of the dimensionless parameters listed in the caption of Figure 9. A linear analysis of most systems of this type will indicate the need for feedback from the control surface position. However, to reduce the system to a basic minimum, this feedback was omitted from the first studies. Under these conditions the general conclusions described for the speed governor were also found to be valid for the auto pilot. The region in which coulomb friction increased damping was much narrower for the auto pilot and no performance that could be considered satisfactory for such systems was obtainable with appreciable coulomb friction. Figure 9*a* is a typical solution of a system undamped without the presence of coulomb friction, but positively damped by the addition of coulomb friction. This set of records is of interest in that the indeterminate and critical nature of the steady-state value of the air frame error angle is shown. As indicated by the equation for the steady-state error angle, given in Figure 4, this value may lie anywhere within the two indicated limits.

The two solutions of Figure 9*a* were obtained by changing very slightly the gain around the complete feed-back loop. In most cases it was found that in a system showing good performance without coulomb friction, the addition of coulomb friction destabilized both the control surface and the airframe. However, there was found to be a limited range in which the addition of coulomb friction actually stabilizes the rudder position, although it causes destabilization of the air frame. This behavior is illustrated in Figure 9*b*, and the limited range was found by varying only the dimensionless parameter $Gk_1k_2/(A_1T_e)$, the performance is still unsatisfactory.

The top four solutions of Figure 9*c* represent a system using feedback from the control surface that provides good performance in the absence of coulomb friction. With coulomb friction added, both the control surface and the air frame are destabilized. As indicated by the bottom set of four solutions, the oscillations produced by coulomb friction could be damped out by readjusting both the parameter *a* and the feed-back constant k_3. In general the destabilizing action of coulomb friction could be eliminated by raising both the anticipation time constant T_a and the gain around the control surface position feed-back loop. For friction ratios as high as 1.7, doubling both the gain around the feed-back loop and the time constant T_a appears to be sufficient in most cases. However, the time of response of the system decreases and steady-state error increases, as shown in Figure 9*c*. Figure 9*d* illustrates a case involving no coulomb friction in which good system performance is obtainable without gain around the rudder position feed-back loop and for which the addition of such a gain has little beneficial effect. This was found to be a general effect when the relative inertia of the control

C—Solution showing effect of increased feed back (k_3) from control surface position to counteract coulomb friction effect

D—Case where coulomb friction destabilizes both control surface and air frame

surface system is low and good damping without rudder position feedback is obtainable.

In the study that was made of the effect of coulomb friction in three basic types of servomechanisms, it was found that the presence of such friction in the follow-up mechanism of a positioning servo always increases the system damping, but also increases the time of response and the steady-state error. The least value of friction ratio that is appreciable in such systems varies with the relative amount of viscous damping, increasing about proportionately with the per cent of critical viscous damping. Its effect is shown in detail in Figure 5. The chattering or grabbing effect described by Den Hartog for a single degree of freedom mechanical system under the action of a sinusoidal applied force was also found to be present in all servomechanisms under the action of both steady-state sinusoidal disturbances and transient disturbances.

In simple speed governors described by a cubic equation, coulomb friction can either increase or decrease the system hunting, depending upon the magnitude of the basic linear parameters of the system. Friction decreases the hunting when the viscous damping in the governor system itself is low, and as long as the disturbance torque does not exceed certain limits, its performance can be considered to be beneficial. In regions where good performance is obtained through sufficient viscous damping or feedback around the governor loop, the presence of coulomb friction can, in general, be considered as harmful. The magnitude of coulomb friction is defined by the friction ratio and the value that is appreciable can best be determined from examination of the typical solutions presented in the paper.

Coulomb friction was found to be generally harmful in the basic auto pilot studied here. The friction would under certain conditions increase the system damping slightly, but in general would decrease damping in both the control surface and the air frame. The destabilizing effect of friction can usually be corrected somewhat by increasing the anticipation time constant T_d and, although only a limited number of cases was studied it is indicated that if the addition of feedback around the control surface loop is beneficial in the linear analysis of the system, good damping, even with the presence of large amounts of coulomb friction, can be achieved by doubling both the anticipation time constant and the gain around this feed-back loop.

Graphical Analysis of Control Systems

WALTER R. EVANS
ASSOCIATE AIEE

Synopsis: The purpose of this paper is to demonstrate some graphical methods for finding the transient response of a control system. A simple position follow-up system is considered for convenience although the method is applicable in the same form for higher order systems or those in which only empirical frequency data is known. The basic procedure is to find the roots of the differential equation which correspond to the exponential transient terms which dominate the response. Doctor Profos[1] of Switzerland points out that the plot of the function which describes the system from error to output is a function of a complex variable of which frequency is the imaginary part and damping is the real part. The Nyquist plot is thus one line of a conformal map with the root of the equation being the value of the variable which makes the function equal to -1. Any line of plot can be calculated for systems with known functions with essentially the same ease as the Nyquist plot by use of some graphical tricks. The amplitude of any transient term is determined from the plot once the root is known by use of a theorem of operational calculus. The development possibilities of the subject seem to be very great as suggested by several topics not yet investigated.

Review of Fundamentals

A QUADRATIC SYSTEM will first be analyzed in order to emphasize the important concepts in finding any transient response. Consider the position follow-up system shown in Figure 1.

The differential equation relating the output to the error is

$$K\epsilon = \left(1+T_M\frac{d}{dt}\right)\frac{d}{dt}\theta_o(t) \qquad (1)$$

K is the output speed corresponding to a unit error. T_M is the time constant of motor acceleration, other delays are neglected. But input is the output plus the error.

$$\theta_i(t) = \theta_o(t) + \epsilon(t) = \left[1+\frac{1}{K}\left(1+T_M\frac{d}{dt}\right)\frac{d}{dt}\right]\theta_o(t) \qquad (2)$$

Consider the input to be a unit step and note that the steady state value of output will also be unity. Assume that the output transient can be represented by exponential terms, so that $\theta_o(t) = Ae^{st}$ is substituted into the differential equation, and the common factor Ae^{st} cancelled.

$$0 = 1+\frac{1}{K}(1+T_M s)s \qquad (3)$$

Note that s appears at each point where d/dt had occurred before. This equation in s is an algebraic one, and any value of s which satisfies it represents an exponential term which can exist in the transient.

Anticipating the fact that s will replace d/dt when an exponential solution is assumed, the system itself can be more conveniently represented by the block diagram of Figure 2. The function in a block represents the ratio of its output to its input. The relationship between θ_i and θ_o can now be set up directly.

$$\frac{\theta_i}{\theta_o} = \frac{\theta_o+\epsilon}{\theta_o} = 1+\frac{\epsilon}{\theta_o} = 1+\frac{1}{K}(1+T_M s)s \qquad (4)$$

For this case of a quadratic equation the roots can be found directly by completing the square and solving for s.

$$s = -\frac{1}{2T_M} \pm j\sqrt{\frac{K}{T_M}-\left(\frac{1}{2T_M}\right)^2} = -\sigma_n \pm j\omega_n \qquad (5)$$

The oscillatory case is taken because it is typical of the response of a fast control system. The transient solution is the sum of two exponentials, one for each root.

$$A_1e^{(-\sigma_n+j\omega_n)t}+A_2e^{(-\sigma_n-j\omega_n)t} \qquad (6)$$

But this can be converted to a cosine function using the relation

$$e^{j\omega t} = \cos\omega t + j\sin\omega t \qquad (7)$$

Select as the new undetermined constants the amplitude A and the phase angle ϕ

$$Ae^{-\sigma_n t}\cos(\omega_n t-\phi) \qquad (8)$$

The constants are determined from the initial conditions that the output is zero and its rate of change is zero at time zero. The complete solution for output then becomes:

$$\theta_o(t) = 1-\left(\frac{1}{\cos\phi}\right)e^{-\sigma_n t}\cos(\omega_n t-\phi); \quad \text{in which } \tan\phi = \frac{\sigma_n}{\omega_n} \qquad (9)$$

The following numerical values are selected for convenience

$$K = 2/\text{seconds} \quad T_M = 1 \text{ second} \qquad (10)$$

Note that if T_M were equal to one-tenth second, the value of θ_i/θ_o given in equation 4 would be the same if s and K were both made ten times larger. Thus, the results of these problems can be shifted into any range of values with which the reader may be normally accustomed. Substituting the foregoing values gives

$$\theta_o(t) = 1-1.07e^{-0.5t}\cos(1.32t-21°) \qquad (11)$$

Graphical Plot to Locate Real Roots

The consideration of an additional delay in the control system raises the degree of the equation from second to third. In this case, consider the delay to be the time constant of the inductive build-up of current in the field of the generator supplying the motor. Setting up the ratio θ_i/θ_o

$$\frac{\theta_i}{\theta_o} = 1+\frac{\epsilon}{\theta_o} = 1+\frac{1}{K}(1+T_G s)(1+T_M s)s \qquad (12)$$

The previous values of $K=2, T_M=1$ will be kept and T_G taken as one-fourth second.

Paper 48-85, recommended by the AIEE basic sciences committee and the joint subcommittee on servomechanisms and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted August 11, 1947; made available for printing December 29, 1947.

WALTER R. EVANS, assistant professor, department of electrical engineering, Washington University, St. Louis, Mo.

Figure 1. Position follow-up system

Figure 2. Simplified block diagram

Complex roots such as those which arose in the quadratic system always occur as a conjugate pair; therefore this third degree equation must have either one or three real roots. In finding the real value of s which makes the function of s of equation 12 equal to zero, one of the reasons for the simplicity of finding roots of a known function will become apparent. The factors of ϵ/θ_o are already known therefore, make $\theta_i/\theta_o = 0$ by making $\epsilon/\theta_o = -1$. In guessing s to be a negative real quantity $-\sigma$, each factor of ϵ/θ_o is a real quantity and can be plotted against $-\sigma$ as shown in Figure 3.

The range of $-\sigma$ from 0 to -1 gives a product of factors which is negative, but the magnitude is a fraction so that a root cannot exist in this region. The region beyond $-\sigma = -4$ certainly contains a root. A guess of $-\sigma = -5$ gives a result of $\epsilon/\theta_o = -2^1/_2$. A second guess of $-\sigma = -4^1/_2$ suggests itself to make $\epsilon/\theta_o = -1$ because the factor $1+T_G S$ is then cut in half whereas the other factors are nearly constant. The new result is $\epsilon/\theta_o = -63/64$ with further correction probably not justified by accuracy of the data. Note the calculation of ϵ/θ_o is very rapid by maintaining the identity of the factors, and that guesses of values of roots are immediately suggested.

Divide by the factor $s+4^1/_2$ to reduce the third degree polynomial to a quadratic. Solve for the complex roots of the quadratic as before to find $s = -0.25 \pm j1.30$. Apply initial conditions to determine the constants to find that the total response is given by

$$\theta_o(t) = 1 - 0.08e^{-4.5t} - 1.036e^{-0.25t} \times \cos(1.30t - 27°) \quad (13)$$

The main effect of considering the second delay is to cut down the damping rate of the oscillation.

Vector Plot of Error–Output Ratio For Sinusoidal Signals

A standard method of counteracting the effect of a time delay is to insert in the amplifier a circuit whose output includes the derivative of error. The form of its output/input function is shown in the block diagram of Figure 4.

The determination of the roots of such a system is generally agreed to be a tedious job by present methods and is infrequently done. The frequency response method instead has been developed to a fine point as indicated by the many recent articles on the subject.[2] In this method the feed-back loop is broken and a sinusoidal signal is impressed. The output is determined in magnitude and phase angle as a function of frequency. This information can be obtained by any one of several calculating methods or by direct laboratory tests. A convenient way to show the results is to plot the vector ratio of error/output. The plot for the foregoing system is shown in Figure 5 with the frequency identified by numbers in parenthesis.

For a stable system, the locus of ϵ/θ_o must swing outside the -1 point, physically meaning that the output/error ratio is a fraction at the frequency such that the output is in phase with the error. The vector ratio of θ_i/θ_o is greater than the ϵ/θ_o ratio by 1 and is therefore a vector to the curve with tail at the -1 point. Increasing the gain to $K=6$ contracts the curve as shown bringing it inside the -1 point indicating an unstable system. An intermediate value of gain $K=3$ contracts the curve in toward -1 point so that one would expect that the system was closer to becoming unstable, or having less damping. A quantitative value of damping, however, is now primarily a matter of experience based on systems with known vector plots and known transient performance. It is precisely at this point that the key idea of Profos becomes effective.

Determination of Principle Roots From Vector Plot

The key idea of P. Profos[1] is to consider the vector plot to be the base line from which the complex roots of the main damped sinusoidal term can be determined. Recall from the simple quadratic system that these roots make the ϵ/θ_o ratio equal -1. These roots could be determined if a plot of the function of s could be made as a function of both $-\sigma$ and ω.

One recognizes a somewhat similar situation in plotting an electrostatic field in which the complex variable involves flux and voltage. The patterns for lines of constant voltage and lines of

Figure 3. Plot to locate real roots

Figure 4. Block diagram of system. Lead circuit added to amplifier. Generator and motor delays considered

flux is known to be a grid of curvilinear squares. If this flux plotting property can be justified for ϵ/θ_o, the root values of $-\sigma_n$ and ω_n can be determined by sketching. The justification is that ϵ/θ_o is a function of s which has a particular derivative with respect to s for any value of s in the region of interest. Thus in Figure 6 the change of ϵ/θ_o along the curve for an increment $\Delta j\omega$ means that the derivative must be located 90 degrees clockwise from this increase. If the change in variable at this point were $-\Delta\sigma$ instead, the change in the ϵ/θ_o function would be opposite in direction to the derivative. The magnitude of the change of the function would be the same for equal small changes $-\Delta\sigma$ or $\Delta j\omega$. Thus for fairly large, but equal changes in $-\sigma$ and ω, a set of curvilinear squares will be formed as indicated by the dotted lines.

Note that this complex plot can be based on an original vector plot obtained from laboratory data as well as from one which is calculated. This is valid however, only for systems which are linear in the test range and the results are applicable only to this linear range. This restriction is necessary because the justification of the curvilinear square pattern is that the derivative of ϵ/θ_o is dependent only on the nature of the signal, not the amplitude.

One can sketch such a grid with more confidence after having calculated a few systems with known functional form. This can be done conveniently by some graphical tricks, as shown in the next section.

Calculation of Complex Plot

First consider the facts about present calculation methods as a function of frequency alone which simplify that task. The ratio of output to input for any one time delay is a vector quantity specified by amplitude and phase angle. The output to input ratio for several time delays in series is then the product of their amplitudes and a sum of their phase angles.

$$(1+j\omega T_1)(1+j\omega T_2) = A_1 e^{j\phi_1} A_2 e^{j\phi_2} = A_1 A_2 e^{j(\phi_1+\phi_2)} \quad (14)$$

If one keeps track of amplitudes logarithmecally, the product can be taken by adding logarithms.

$$\log A_1 A_2 = \log A_1 + \log A_2 \quad (15)$$

The logarithmic scale commonly used is the decibel scale defined by the equation below.

$$\text{decibel} = 20 \log_{10} A \quad (16)$$

The new problem introduced is to express any one term $1+T_s$ as an amplitude and phase angle. Several schemes are of course possible, but the following is believed to be the most convenient. Consider the term to be factored as shown below with the T factors saved for later consideration.

$$1+Ts = T\left(\frac{1}{T}+s\right) \quad (17)$$

The term s can be located as a vector from the origin. The complete vector is one with tail at the $-1/T$ point and head at the s point. This vector can be measured by a protractor pivoted at the $-1/T$ point with scale in line with the s point. The amplitude is desired in decibels so the scale is so marked. This scale can be checked by noting the magnitude of 1 is marked as 0 decibel and the magnitude of 2 as 6 decibels in Figure 7.

The case of a quadratic term in the ϵ/θ_o ratio frequently arises. Such a term can be broken into two factors having conjugate complex roots as shown below.

$$S^2+as+b = [S-(-\alpha+j\beta)][S-(-\alpha-j\beta)] \quad (18)$$

These conjugate roots are thus the pivot points for the protractor in making measurements to the s point.

The procedure is now simply one of tabulating decibels and angles for each term, adding decibels for the total decibels, and adding angles for the total angle of the ϵ/θ_o ratio. The over-all amplitude factor for the product can now be established by checking the special case of s is equal to 0. The value of ϵ/θ_o for $s=o$, eliminating K and s factors is 1 as shown in the block diagram. The sum of the decibels reading with protractor swung to the origin actually obtained is due to all of the factors accumulated in setting up the $1/T+s$ vectors. This decibel value should be subtracted from all sums obtained for other values of s. Division by the gain K is achieved by subtracting the decibels for that K from the net decibels previously obtained. The ϵ/θ_o vector is then known as an angle and decibels of magnitude and so can be plotted using the same protractor.

It is convenient to make the first calculation for constant values of $-\sigma$ and the uniform changes in $j\omega$. Thus a curvilinear square pattern should be formed with any mistake in calculating one point showing up by its failure to be in line with the grid set up by the other points. The plot for the system of Figure 4 is shown in Figure 6 for $T_C=1/2$ and $K=4$. The

Figure 5. Vector plot of error/output ratio with sinusoidal signal impressed

Figure 6. Complex plot for system. Conformal map properties are indicated. Root at $s=-\sigma_n \pm j\omega_n = -0.95+j2.25$

value of s which makes $\epsilon/\theta_o = -1$ is $s = -\sigma_n \pm j\omega_n = -0.95 \pm j2.25$. The amplitude of the transient having this root as well as its initial phase angle, needs to be determined before the transient can be plotted. Fortunately this is possible without need for finding the rest of the roots and substituting initial conditions by means of a theorem of operational calculus.

Amplitudes From Operational Calculus

The concept of s thus far presented has been simply that of being a complex number used in the exponential solution of the differential equation. This concept is sufficient for explaining the process of finding the roots to the equation. The symbol s, however, has a more potent significance as it is used in operational methods such as the Laplace Transform.[3] Those familiar with these methods of course realize that this is a long study in itself, but essentially only one fact need be used. The amplitude of any transient term is given in terms of its root by

$$A_1 = \frac{1}{s\left.\frac{d}{ds}\left(\frac{\theta_i}{\theta_o}\right)\right]_{s=s_1}} \tag{19}$$

But the derivative of the function can be determined directly from the complex plot. It is vector with an angle of 84 degrees as shown in Figure 6. The magnitude is the change in ϵ/θ_o divided by the change in s. An average of several measurements in the region of the -1 point gives the value of 0.60.

The two transient terms involving the pair of complex roots can be converted into a single term as in the simple quadratic system. The conversion is made very rapid by noting that the amplitude terms are conjugates of each other. In taking the sum therefore their real parts add and their imaginary parts cancel. The result can thus be written as twice the real part of one of them.

$$2R\left[\frac{e^{-\sigma_n t}e^{j\omega_n t}}{ae^{j\alpha}be^{j\beta}}\right] = \frac{2e^{-\sigma_n t}\cos\ (\omega_n t - \alpha - \beta)}{ab} \tag{20}$$

in which

$$ae^{j\alpha} = s = -\sigma_n + j\omega_n$$

and

$$be^{j\beta} = \left.\frac{d}{ds}\left(\frac{\theta_i}{\theta_o}\right)\right]_{s=-\sigma_n+j\omega_n}$$

The other two roots to this fourth degree system are found to be real roots of -2.58 and -16.6. The derivatives can be found by any one of several methods but from the slope of the function they are -1.45 and $+1.66$, respectively. The complete solution including the steady state value of 1 becomes:

$$\theta_o(t) = 1 - 1.36e^{-0.95t}\cos\ (2.25t - 17°) + 0.267e^{-2.58t} - 0.036e^{-16.6t} \tag{21}$$

Procedure For Complicated Systems

A solution of a fourth degree equation is nothing new, but this method can readily be applied to higher order equations. Thus additional time delays or stabilization circuits will distort the frequency locus but the conformal map can still be sketched.

The quadratic roots found from the original plot represent the transient term which will frequently dominate the complete transient response. If a complete solution is desired, however, these known factors can be divided out of the θ_i/θ_o ratio. Thus, for any value of frequency, the angle and decibels readings for the protractors pivoted at the conjugate root points, with the scale at the frequency point, should be subtracted from those of original vector to obtain those of the new vector. Note that in general the portion of the original vector plot for higher frequency values will now be contracted into the -1 region. Thus, one would have to have frequency data in the region of the higher order roots in order to find them. Usually the corresponding transient term will be found to damp out rapidly so that they would be needed only to study the initial break away of the output. It is probable that other methods would be more applicable to studying this region.

The construction of a vector plot for a multiple loop system can be readily carried out on a completely vector basis. The multiplication process has already been shown, and the addition process is simply the familiar completion of a parallelogram. Many time saving tricks are possible however by shifting or rotating an entire plot with respect to its previous position. The predominance of feed-back signals over feed-forward signals makes the inverse plot more convenient, for starting at the output one can build up a diagram back to the input step by step.

Occasionally systems will have two pairs of quadratic roots in about the same frequency range. The Nyquist plot then circles the -1 point with the result that a plot built up from one side overlaps a plot built up from the other side. This situation can be handled by a process of successive approximations. Start with the pair of complex roots suggested by the plot built from one side and divide the function by these factors. The resultant plot will usually give good indication of the other pair of roots since overlapping is eliminated. The first pair of roots may now be determined more accurately by dividing the original plot by the factors corresponding to the second pair of roots.

For systems in which the damping is near critical, the behavior of the plot near the origin must be understood. A good example to work out is for a simple quadratic with roots of $-1 \pm j^1$. The first "square" is shaped like a triangle with base from 0 to -1, and curved sides crossing at $-1/2 + j^1$. The missing corner will be found to be at the midpoint of the 0 to -1 line.

Protractor measurements could be eliminated by substituting potentiometers at the pivot point which turn in resistance proportional to angle. The decibel readings could similarly be replaced with potentiometers which are turned as a logarithmetic function of the distance to the s point. Connecting each set of potentiometers in series will then give total angle and total decibels as resistances. These resistances could then be used as inputs to instrument servos which could actuate meters or locate the position of a pen.

Development Possibilities

What are the possibilities for new types of laboratory tests to give empirical data other than just frequency response? The problem would seem to be primarily one of achieving a steady state condition long enough to get a reading and not have the natural transient of the system present. An exponential build-up might work in that starting from zero the transient should not appear and the only reading necessary is the ratio of output to input, which should be constant during the build-up. An exponentially increasing sine wave would correspond to a complex value of s, though the reading here would have to include phase angle as well as magnitude.

The similarities of the conformal mapping properties of static fields and these functions of s seem to offer the most interesting possibilities. Conceivably the known system information could be set up as boundary conditions of an electrostatic field so that the pattern of equipotential lines and lines of flux would correspond to the system plot. The system plots of the type described in this paper

Figure 7. Vector determination of $1/T+s$

however, have several values of s which makes the ϵ/θ_o equal to -1 where as only one voltage could exist at the -1 point for the field. Another system plot is possible however in which the roles of ϵ/θ_o and s are reversed. Any point on the plane would correspond to a value of s and ϵ/θ_o is plotted as loci of its constant real part and constant imaginary part.

A physical picture of the plot can be gained by considering a surveying contour map in which lines of constant altitude correspond to constant real part and lines of maximum slope correspond to lines of constant imaginary part. On this basis a quadratic function in the region of the roots has the shape of a horse's saddle. Imagine a view of the saddle from above with the origin at the horn of the saddle and the $-\sigma$ axis running straight back to the rear. One trace of zero imaginary part is along this axis and the other intersects it at right angles at the center of the saddle. Picture now the saddle to be immersed in water and gradually lifted out. The water level lines on the saddle give the locus for a real part of $\epsilon/\theta_o = -1$ as the gain of the servo is increased. In this situation the roots of the transient equation lie at the intersection of the locus for a real part of $\epsilon/\theta_o = -1$ and the locus for zero imaginary part. These roots therefore move down the saddle from the horn and the rear until they meet in the center for the critical damping case. Further increase in gain, or raising of the saddle, causes the roots to appear as a conjugate pair moving down each side toward the stirrups.

Will a static field be capable of mapping such a pattern? If so, what boundary conditions will be necessary? This seemingly never-ending chain of questions serves to keep the subject interesting, since one does not know what useful method might be encountered in the process of finding the answers.

Crystal Filters Using Ethylene Diamine Tartrate in Place of Quartz

E. S. WILLIS
MEMBER AIEE

Synopsis: Ethylene diamine tartrate (EDT) crystal filters were developed to replace the earlier quartz type channel filters in the broad band carrier telephone systems, because of the threatened scarcity of quartz. These new filters give performance comparable to that of the earlier design. The growth of the EDT crystals from seeds and their fabrication into crystal units for use in filters are covered in companion papers on "Design and Performance of Ethylene Diamine Tartrate Crystal Units"[6] and "Growing Crystals of Ethylene Diamine Tartrate."[7]

UNUSUAL RESULTS are often realized in the search for improved methods of providing economical telephone communication. The commercial application of ethylene diamine tartrate (EDT) crystal units to electric wave filters for use in carrier telephone systems was one such development. The immediate urge for this development was the postwar need for an enormous increase in long distance telephone channels. Whereas the prewar program called for the addition of about 400 long distance channels annually, it was evident, soon after V-J day, that the postwar program would call for about 10,000 such channels annually.

New long distance channels are provided in the telephone plant by the broad band carrier systems[1,2,3] the designs of which are based on handling a bank of twelve speech channels as a unit. These 12 channels make efficient use of the available frequency space by using only 4 kc for each speech channel. High quality transmission is realized by the use of filters having sharp cut-off characteristics. Hence, the filters used to separate channels, to supply the carrier frequencies, and to supply and pick off the pilot frequencies all have been filters employing quartz crystal units.

During the latter part of 1945 it appeared that the expansion of long distance facilities would be curtailed due to the scarcity of quartz. The anticipated quartz demand was approximately ten times the prewar imports from Brazil and it was estimated that such quartz, suitable for telephone applications, as was left over from the war effort soon would be exhausted and the manufacture of broad-band carrier systems cease unless prompt measures were taken to remedy the situation. This emergency was met ultimately by the use of EDT crystal filters developed principally as the result of the forward looking research program of the Bell System under which piezoelectric materials have been under investigation for more than 25 years.

In order to allow time for the development and manufacture of EDT crystal filters for commercial service the following measures were taken to provide immediate relief to the critical quartz situation:

1. It was found possible to stimulate the rate of quartz purchases from Brazil.

2. More efficient use was made of the available quartz.

During the period of 1938 to 1942 annual imports of 5,000 to 7,000 pounds of quartz, of a size suitable for use in filters, were sufficient to meet the yearly demands of the Bell System. At the beginning of 1946 the outlook was that imports might be stimulated to reach a maximum of 20,000 pounds annually. Even with this optimistic estimate only about 1/4 of the quartz demand could be supplied. The use of more efficient cutting tools and improvements in manufacturing techniques introduced during 1946 resulted in a marked increase in yield of quartz plates per pound of quartz and further reduced the spread between supply and demand. These steps resulted in stretching the availability of quartz and will make it possible to carry out an orderly shift from quartz to EDT without requiring any significant drop in the rate of supplying broad-band carrier systems.

The decision to develop EDT crystal filters as a permanent means for relieving the quartz shortage was made after conducting an extensive survey. This included an analysis of the need for quartz for various filter functions, and a consideration of alternate means for accomplishing these same objectives while either eliminating or greatly reducing the use of quartz. Seventy-five per cent of the quartz required for telephone use is utilized in the manufacture of the channel selecting filters in broad-band carrier systems. There are 12 of these filters operating in the frequency range of 60 to 108-kc and the channels with which they are associated are numbered 1 to 12, inclusive, starting at the 108-kc end of the frequency band. The lower frequency filters of the group, channels 9 to 12 inclusive, require the larger size quartz plates; hence, they account for a large portion of the quartz demand.

Large quantities of quartz also are required for the pilot pick-off filters in the carrier on cable systems. There are three of these filter designs passing narrow bands of frequencies at 12-kc, 28-kc and 56-kc, respectively. They each require large quartz plates which can be obtained

Figure 1. Schematic circuit of the 56-kc pilot pick-off filter (246A)

Paper 48-86, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 13, 1947; made available for printing December 8, 1947.

Figure 2. The 246A filter picks off the 56-kc pilot signal without disturbing the modulated speech signals carried on the line

Figure 3. With wide fluctuations in temperature the loss at 56 kc remains practically constant

only from the extremely scarce large size crystals. Of these three the 56-kc filter requires the most quartz; hence, it was placed next to the channel filters on the list of filters to be redesigned or replaced in order to reduce the demand for quartz.

The means for reducing quartz demands centered about possible modifications of the bank of 12 channel filters. Several proposals were considered involving either, the use of quartz type filters operating at higher frequencies where the size of the quartz plates would be greatly reduced, or the use of coil and condenser filters. In either case additional stages of group modulation would have been required, necessitating additional central office equipment. These proposals were discarded as being too costly in manufacturing effort and office space required. The most attractive proposition involved the redesign of the 12 channel filters to use EDT crystal units in place of the quartz units. This not only maintained the same operating frequency range as the present circuits but also provided the following advantages:

1. The EDT filters would be designed to meet practically the same electrical requirements as the quartz filters, thereby requiring only minor systems circuit changes.

2. The EDT filters would occupy the same mounting space as the quartz filters, eliminating the need for extensive equipment design changes.

3. An independent source of piezo-active material would be provided so that growth of the long distance facilities in the future will not be restricted by the inability to import sufficient quartz.

It was felt that the stockpile of quartz would be extended sufficiently to permit the orderly completion of this development without creating a break in the manufacture of broad-band carrier systems.

After the decision to develop EDT crystal units for use in channel filters had been reached it appeared relatively straightforward also to apply EDT crystal units to the 56-kc pilot pick-off filters. The selection of the type of crystal cut for use in a particular filter is based on the use to which the filter is put. The pilot pick-off filter is designed to select a narrow band of frequencies around 56 kc and maintain practically constant loss to these frequencies with temperature variations and aging. This filter is used in central offices and in attended repeater stations, hence the temperature range is about 70 to 110 degrees Fahrenheit. The *A*-cut EDT crystal unit, which is very stable with temperature changes in the region of room temperature, was selected for use in this filter. The *Y*-cut EDT crystal unit, because of its low equivalent inductance, was selected for use in the lower frequency channel filters that is, channels 7 to 12, inclusive. In order to expedite the introduction of EDT crystal units and filters in manufacture, the filters for channels 1 to 6, inclusive were originally designed to utilize quartz crystal units. The selection of the specific cut of EDT crystal unit for substitution in these filters has not been made.

Figure 4. Schematic circuit of the crystal channel filter (239 type)

56-Kc Pilot Pick-Off Filter

The 56-kc pilot pick-off filter (*246A*) consists of two EDT crystal units and three fixed condensers as shown by the schematic of Figure 1. The greater piezoelectric effect of EDT crystals made possible the use of a simpler type of filter structure than was used in the earlier quartz filter (*226C*) which it replaces. The two crystal units required in the filter are identical and they are 2-terminal units rather than the more complicated 4-terminal units used in the quartz design. The insertion loss frequency characteristic shown in Figure 2 is similar to that of the quartz filter. The filter mounts interchangeably with the quartz filter and, as with the earlier design, two filters are connected in tandem in each twist amplifier of the cable carrier system to select the pilot frequency and suppress adjacent bands. Any combination of quartz and/or EDT filters may be used satisfactorily in the system.

The 56-kc pilot frequency is used to regulate the gain of the twist amplifier and any changes in the pass band loss of the filters are reflected as errors in the regulation of the amplifier. Therefore, it is desirable to maintain the loss of the filter at 56 kc as constant as possible with temperature variations The temperature coefficient of the EDT crystal units

used in this filter is such that the pass band of the filter shifts down in frequency as the temperature increases and at the same time the pass band loss increases due to a decrease in the Q of the crystal units. Accordingly, the filter as designed by G. H. Lovell, utilizes these two effects to maintain approximately constant loss at 56 kc with temperature change. At normal temperature the 56-kc frequency rides on the top of an attenuation bump in the filter pass band. With the increases in temperature which may be encountered, the pass band shifts down in frequency causing the loss at the 56-kc frequency to slide down from its location at the top of the bump but the accompanying decrease in Q of the crystal unit produces an increase in loss over the entire pass band, thereby maintaining the loss at 56 kc practically constant with temperature change. The change in loss with temperature change from 75 to 110 degrees Fahrenheit is shown in Figure 3. For two filters in tandem this amounts to only 0.15 decibel at the 56-kc frequency.

Channel Filters

The EDT crystal channel filters (239 type) were designed to replace the earlier quartz type filters[4] (219 type) in broad band carrier systems. They mount interchangeably with the earlier filters. In order to permit the placing of wider tolerance on the inductance and resonant frequency of the crystal units, these filters were designed as two-section rather than one-section lattice type filters. However, instead of using four retardation coils as was done in the earliest crystal channel filter[5] (75 type) only three coils per filter were used. The two center series coils were replaced by one shunt type coil. This not only permitted the assembly of the filter in the same size container as the 219 type and kept the pass band loss level of the two designs the same but also brought about a reduction in manufacturing effort. The schematic is shown in Figure 4. A typical insertion loss characteristic is shown in Figure 5. The edges of the pass band are somewhat more rounded than the earlier designs. However, the same type of channel performance in the telephone system will be obtained by shaping the characteristic of the voice frequency amplifier at the receiving terminal to effectively widen the channel band.

The elements that make up the filter are assembled on a chassis as shown in Figure 6. These elements consist of crystal units, retardation coils, adjustable air and fixed mica capacitors, and deposited carbon resistors. There are four Y-cut EDT crystal units each mounted in an evacuated sealed glass envelope. The metallic coating on each major surface of the crystal plate is divided longitudinally by a fine line to provide two identical electrical structures in each balanced crystal unit. These Y-cut units have a temperature coefficient which is zero a little above room temperature and increases to about 10 parts per million per degree Fahrenheit at the extremes of temperature encountered in the central offices. This is in contrast to the 15 parts per million for the -18 degree X-cut quartz units used in the earlier filters. The dissipation associated with the EDT crystal units is somewhat greater than that encountered in the corresponding quartz units. However, the crystal unit Q's of 15,000 to 20,000 are sufficient to provide the sharp cutoffs desired in these filters. A more detailed description of the construction and performance of these units is included in a paper[6] by J. P. Griffin and E. S. Pennell

Figure 6. Filter parts are compactly assembled and wired on a chassis, the air capacitors are adjusted, and the unit is hermetically sealed in the filter container

The growing of EDT crystal is covered in another paper[7] by A. C. Walker and G. T. Kohman.

There are three retardation coils,[8] ranging in inductance values from 15 to 40 millihenrys, used in this filter. They are toroidal coils wound on rings of molybdenum permalloy approximately one and three fourths inch in diameter. The core material has been so designed that the coils give stable performance with temperature changes and over the expected life of the apparatus. Eddy current losses in the cores are reduced by the use of very finely powdered magnetic particles in their formation. The cores are formed under extreme pressure from a mixture of this powder and insulating material. The coils are wound with finely stranded wire to secure relatively high Q's at the frequencies at which they are to operate. The coil winding is divided into four sections as shown in Figure 7. Because of the high coil inductances called for by the filter design, care is taken to make the parasitic capacitances between windings and between windings and the case as low as practicable. A molded framework placed around the core reduces the capacitance from windings to core and improves the uniformity of the sectionalized windings. This framework also locates the coil centrally in its container keeping the capacitance from windings to case uniform. The final operation in the con-

Figure 5 (left). Insertion - loss - frequency characteristics of the 12 channel filters are the same, when plotted in cycles removed from the carrier frequencies

Figure 7. Toroidally wound coil is located centrally in its hermetically sealed container

Figure 8. Two-terminal network connected across the paralleled end of the group of 12 filters to make the transmission through the two end channels of the group equal to that through the others

struction of the coil consists of vacuum drying and wax filling followed immediately by hermetic sealing. The resulting coil is highly stable, having a negative temperature coefficient of approximately 30 parts per million per degree Fahrenheit.

Three of the adjustable capacitors along with their associated molded silvered mica[9] capacitors provide the shunt capacitance at the input and output of each lattice. The other two adjustable capacitors are differential type and they provide adjustments for each of the lattice bridge circuits thereby permitting the location of two of the filter attenuation peaks at discrete frequencies.

Resistors are used to regulate the loss level so that the pass band losses of the 12 filters are approximately the same. This band loss is contributed mainly by the dissipation associated with the retardation coils and, to have equal losses in the 12 filters, the Q's of all the coils should be directly proportional to the frequency of operation. Since for economical reasons the coils were not designed to meet this restriction, resistors are added in series with the coils to regulate dissipation. The resistors for the end coil have been combined with a resistance pad, the value of which may be varied to keep the pass band loss at the desired level. The resistors are the deposited carbon type and are approximately 7/8 inch long and 7/32 inch in diameter.

It is the function of these filters to combine the modulated speech bands from 12 subscribers sets for transmission on the line and, at the receiving terminal, to separate these same bands so that they may be sent on to the proper subscribers sets. Hence, in operation these 12 filters are connected in parallel at one end. The impedance at this end of each filter is made to rise sharply in absolute value away from the filter pass band, thereby reducing the shunting effect of the paralleling filters over the band of the transmitting filter. The two series condensers at the input of the filter are included in the design for the purpose of increasing the slope of this impedance curve. In operation a two terminal network shown in Figure 8 is connected across the paralleled filters for the purpose of reducing this shunting effect over the pass bands of the two end filters of the group.

The development of EDT crystal units has provided the filter engineer with a new design tool that will widen the field of application of crystal units to filters. The lower value for the ratio of capacitances obtained with EDT crystal units, in contrast to quartz as stated in the paper by Griffin and Pennell[8] makes possible the design of crystal filters having wider pass bands. The maximum percentage band width, that is, the ratio of band width to midband frequency, obtainable with filters using quartz crystal units and condensers only is 0.72 per cent. This value is increased to 3.0 per cent when the quartz units are replaced by EDT. In order to get still wider bands it is necessary to employ coils as well as crystal units and condensers in their construction. However, the 14.0 per cent maximum possible band widths thus obtained with the quartz units is often a restriction on the use of wide band crystal filters. The 30.0 per cent possible with EDT units will open a wider field of application.

Ethylene diamine tartrate crystal filters are being used in commercial service at widely distributed locations in the Bell Telephone System as indicated on the map, Figure 9. They consist of approximately 100 models each of the twelfth channel and 56-kc filters which were constructed and put into service during the past 18 months on a trial basis. The filters were sent to the field in a large number of shipments using the same packing methods which have been used with success on quartz filters and they were

Figure 9. EDT crystal filters are operating in commercial service in the cities indicated

Two New York-St. Louis cable carrier circuits are completely equipped with both channel filters and 56-kc pilot pick-off filters

subjected to a wide variety of weather and handling conditions. The results of this trial have been most gratifying, indicating that these filters are satisfactory for commercial service and that special methods of handling will not be required.

The development of the EDT crystal unit and its application to filter circuits has provided the Bell Telephone System with an independent source of piezo-active material that is suitable for use in filter circuits. This came at a time when it appeared likely that the provision of urgently needed telephone service for the public would be restricted by the inability to import quartz in sufficient quantities to meet the needs.

E. S. PENNELL
NONMEMBER AIEE

A COMPANION PAPER[1] describes the need for development of a substitute for quartz in the crystal units used for filters in broad-band carrier telephone systems. It was fortunate that the research work of the Laboratories[2,3,4] on piezoelectric materials, both natural and synthetic, had arrived at a stage where a suitable material was available. Such a material had to be composed of readily available raw materials, susceptible to growth in reasonable time, not too delicate to be handled, with good piezoelectric qualities and particularly to have constants which would not vary too much with temperature over the range usually encountered in telephone central offices. Quartz had admirably fulfilled all of the above conditions except procurement. With the post war expansion of needs it has become increasingly difficult to obtain quartz in adequate quantities from Brazil making it necessary to find an acceptable replacement. Rochelle salt and ammonium dihydrogen phosphate, ADP,[5] although suitable in many ways were not satisfactory from the standpoint of frequency stability with temperature changes. Two other materials, dipotassium tartrate hemihydrate, DKT, and ethylene diamine tartrate, EDT, were found in the course of Laboratories investigations to show promise of meeting the necessary requirements for crystal units. Of these two, EDT was chosen since it appeared that it could be more easily grown and processed in commercial quantities. This material was transformed from an experiment into a commercial reality during the two years 1945 and 1946. The development of this essential and valuable network element involved many unusual phases not generally associated with important inventions. The methods of producing the EDT crystal bars are discussed in a companion paper.[6]

The EDT crystals grow in the form shown in Figure 1. The controlled growing conditions that have been perfected result in clear bars up to 7 inches in length having the faces shown in the sketch. These faces are ordinarily accurate enough for reference in cutting operations but can be ground true on suitable machines if necessary after X-ray correction. The atomic spacings are different from quartz, but the copper target X-ray equipment which has been developed for quartz can be used for EDT correction purposes. The material is easily worked on belt sanding equipment; however, there is a prominent cleavage plane parallel to one of the large faces of the crystal which sometimes causes breakage when grinding thin sections. Its thermal expansion properties are such that breakage can result from rapid or localized temperature changes and crystals as well as wafered material have been cracked merely by holding with the bare hands or by placing them on a cold surface. Nevertheless, changes in temperature can be tolerated even in large sized bars if the temperature is changed uniformly throughout the material and not too rapidly. The material is water soluble and water alcohol solutions are conveniently used for etching purposes. These characteristic properties of EDT have necessitated the development of cutting and processing procedures especially adapted to this material.

Like quartz, the electrical characteristics of an EDT crystal plate vary with its angle of cut and dimensional ratios. These variations are an advantage to the filter engineer since they permit him considerable freedom in selecting configurations of network elements and crystal units. The crystal characteristics of interest in filters are the resonant frequencies, impedance level, temperature coefficients of frequency and the equivalent series and parallel capacities of the finished crystal unit. An examination of the variables entering into these attributes shows that the design of a particular crystal unit cannot be taken too casually.

Various resonances occur in a crystal plate in response to an electrical stimulus because of its piezoelectric and elastic properties. When an alternating voltage is applied to the plate an array of strains occur which are manifested as mechanical distortions of forms determined by the elastic compliances of the crystal. Two basic types of resonance are the longitudinal or extensional and the shear or rhombic distortion. Longitudinal resonances occur in combination in the length, width and thickness; shear resonances occur in the face and edge planes. Other vibrations such as flexural and torsional are excited by the longitudinal and shear piezoelectric drives with frequencies determined by the elastic compliances. All the fundamental resonances may also exist in the form of harmonics or overtones. Since a crystal may vibrate in these many different ways, the name assigned to a given unit arises not only from the angles

Figure 2. Equivalent circuit and reactance of a piezoelectric crystal

Figure 4. Unwanted resonances in EDT

of cut, but also from the fact that the crystal in question is dimensioned and mounted to best utilize a particular type of vibration. The lengthwise longitudinal resonance is usually selected for low frequency work. An example of this is the *A* cut longitudinal EDT plate used in single frequency pilot filters.

The reactance spectrum in the region of any of the several resonances of a crystal is shown in Figure 2*b* and the equivalent electrical network in Figure 2*a*. The resultant equivalent network is handled as a real but inseparable network of four elements whose values are not only known but are controllable within useful bounds.

The EDT crystals now used in the communications field are principally in the channel filters used in the broad-band carrier system filters described in a companion paper. The channel filters described are spaced at 4-kc intervals in the 60 to 108 kc frequency range and the pilot filter passes a narrow frequency band at 56 kc. Over this frequency range the longitudinal mode is utilized to assure a plate of reasonable size and shape that will provide the desired impedance level, dissipation constant, ratio of capacities, and stability when it is suitably mounted and dimensioned. Independent adjustment of frequency and series inductance L_1, Figure 2*a*, is possible in longitudinal plates since frequency is primarily a length function and inductance a thickness function. It should be pointed out that the nominal inductance of EDT is about one-third that of quartz. This is of considerable importance in filters since it leads to better impedance conditions in their design. The ratio of capacities, $r = C_0/C_1$, Figure 2*a*, is a measure of the separation of the resonant and antiresonant frequencies and may be regarded as a figure of merit in network design. The pass band width of the simplest narrow band filters is inversely related to the r of the crystal. For this reason EDT has about a four to one advantage over quartz for use in such networks and also means that for a given width-length ratio a lower impedance level can be secured. These same factors operating in wide band filter design result in band widths double those obtainable with quartz. Although the inherent Q of a crystal is very high considerable degradation results from the way in which they are necessarily mounted. The dissipation factor $Q(=\omega L/R)$ for EDT is about 30,000. This value is about half that of a comparable quartz crystal but is satisfactory for most filter use since about 10,000 is usually considered sufficient.

Temperature coefficients of frequency are related fundamentally to a variety of factors but for this purpose it is sufficient to state that in the useful cuts of EDT the shape of the frequency curve with temperature is that of a parabola concave

Figure 3 (left). Frequency change with temperature

Figure 5. Cutting EDT with a wet string saw

Figure 6. EDT crystal cut to yield seeds and wafers

downward. The zero coefficient portion of the curve as shown by Figure 3 lies at about 27 degrees centigrade, the curve then slopes off to 25 parts per million per degree centigrade at 5 and 45 degrees centigrade. This figure of 25 parts per million at the extreme temperatures is about equal to the coefficient of a −18 degree quartz plate over the whole useful temperature range. Other cuts of quartz are superior in temperature coefficient but cannot be compared for low frequency use since they are not obtainable as equivalent crystals.

So far the discussion has covered only an individual resonance and its characteristics. The design problem grows more complex, however, when it is observed that every plate may vibrate in a number of different ways and in overtones thereof and that some of these modes couple with others to drive new ones. A plot of a few such resonances and how they vary with a dimensional ratio is shown in Figure 4. This plot was taken from an actual dimensioning study to find a suitable plate for filter use. The array of curves shown is only one member of a family that is dependent on width-length ratio. It can now be seen that if a crystal plate is to be selected for a band pass filter, for example, it is necessary to not only assign length, width, thickness and orientation angles to give the right fundamental frequency, inductance and ratio of capacities but coincidentally to find a combination of dimensions that provides an acceptable relative disposition of the unwanted and desired resonances. After determining the required angles and dimensions, it is necessary to prepare plates from which test models can be built and statistical data secured for establishing tolerances.

The steps in cutting EDT crystal plates for processing into crystal units differ in many ways from those for quartz. For example, to guard against heat shock the cutting operations are conducted in air conditioned work space and the temperature of the material is allowed to equalize in the room before handling. The cutting and wafering is performed by a wet string type of saw which cuts by dissolving the material locally along the cutting line. This machine is illustrated in Figure 5. The string saw consists of one or more endless strings running over pulleys to give a taut vertical section similar to a ganged band saw. The EDT crystal is fed against the moving vertical strings which are saturated by passing through a pan of temperature controlled water. A machine of this sort must be utilized since the equipment used in cutting quartz and similar hard materials generates enough heat at the cutting edges to crack EDT. The material is cut to supply seeds for replanting and wafers for subsequent processing into individual plates, as illustrated in Figure 6. After cutting the seeds are drilled to facilitate replanting in the growing tanks. The seed caps C_1 and C_2 are planted directly for growing clear crystal material. The seed plates P_1 to P_n and the end plate P_e are subjected to a capping operation to give seed caps equivalent to C_1. The usable material may be wafered for any specified orientation by using the correct type of holding fixture on the saw table. Wafering for crystal plates is done on a multistring setup which allows a bar to be completely wafered with a single pass of the saw table. A comb type of holding fixture assures the proper orientation of the bar on the saw table as the strings cut along the teeth of the comb. The resulting wafers have smooth faces and can be held to angle tolerances of approximately 30 minutes. Figure 5 shows this operation for the A cut of wafer. For the Y cut wafer the cut is made at right angles to the length of the crystal bar. The cutting rate is approximately 30 minutes per inch of feed. Where material of a size to give 10 wafers is cut on the multistring saw this corresponds to 3 minutes per wafer-inch.

Following cutting, the wafers are rough ground to give a flat face and a straight edge and then X-ray checked for face and edge orientation. Out-of-limit wafers are corrected on adjustable X-ray fixtures and then ground to give true faces and edges. The X-ray fixtures used in checking and correcting wafers are similar to those used for corresponding operations on quartz.

Wafers can be cut to approximate plate size by the simple operation of scribing to a line, with a sharp pointed scriber, and breaking in much the same manner that glass is cut.

The grinding operations are performed on a wet belt sander equipped with accurate ways and holding fixtures. To prevent local heating a liquid coolant is used. For continuous operation, cooling coils or adequate liquid capacity are needed to keep all parts of the machine within a few degrees of room temperature. Rough grinding operations are done with coarse belts of about 200 mesh. Final dimensioning, by paralleling to trued faces and edges, is done with much finer belts. To avoid breakage of the material, a belt is needed which is free from appreciable thickness variation at the joint. These grinding operations are capable of

Figure 7. Typical EDT crystal unit

Figure 8 (left). Gold evaporation chamber with EDT plates in position

Figure 9. Fastax camera shot of EDT breaking during impact test

producing finished crystal plates to orientation tolerances of 30 minutes and dimensional tolerances of 2 mils.

Processing the plates into finished crystal units shown in Figure 7 now begins. The first steps consist of etching the plates in a solution of alcohol and water and attachment of four-headed terminal wires by a cementing process. These wires are only 8 mils in diameter yet can sustain a load of about 7 to 8 pounds. They are located in pairs on opposite sides near the center of the plate. Each wire attachment is subjected to a 500-gram static pull test. It is interesting to note that although the EDT material is weak, ultimate strengths of the wire to plate attachment of 3,000 to 4,000 pounds per square inch have been recorded.

The plate, with wires attached, is coated with a thin film of gold only a few hundred thousandths of an inch thick by an evaporation process in the vacuum chamber illustrated by Figure 8. A notable feature of this process is suspension of the crystals by their wires to permit simultaneous plating of both sides and to avoid unequalized temperatures. By this means the 180 degree centigrade level required for degassing is permissible although such temperatures would otherwise result in cracks and wire attachment failures. Care must be taken to insure electrical continuity from this electrode plating to the terminal wires. Gold is unavoidably deposited on all surfaces of the plate, therefore, the four edges must later be stripped of gold to insulate from each other the electrodes on the two faces. Although the plating appears dense and impervious it can easily be removed by a single pass on a dampened cloth. On some plates, where it is desired to have two separate electrodes on each major surface, the coating is divided along the lengthwise centerline. A small solder weight is attached to each terminal wire at an odd quarter wave length point[7] along its length. This reduces transmission of energy from the vibrating plate through the terminal wires to the supporting cage where it would be dissipated with resultant degradation in Q.

Frequency adjustment is accomplished by reducing the length of the plate—initially dimensioned somewhat longer than the theoretical correct length—by grinding the end of the plate by hand or machine on a fine dry abrasive paper. After adjustment, the crystal plate is mounted in a suitable cage. For this operation the plate is temporarily held in position by means of paper shims while the terminal wires are soldered to the uprights. The shims are then removed, leaving the plate centrally located and supported by its four fine wires. Movement of the plate is restricted to about 25 mils by the use of suitable bumpers that are an integral part of the cage. A complete description of similar techniques used in fabricating quartz crystal units is given by R. M. C. Greenidge.[8]

The cage assembly is sealed in a standard glass vacuum tube bulb and then evacuated and based to result in the completed EDT crystal unit which is then subjected to final tests.

Since EDT is such a new and vulnerable material, fairly elaborate testing has been going on continuously since early 1946 to help devise improved plate mountings that insure safe shipment and to determine the practical limitations imposed by the coefficients of thermal expansion. This testing program in the past twelve months has involved over 100,000 individual measurements of temperature coefficients, mechanical and thermal shock effects, vibration, aging and current capacity. These measurements show that a typical EDT crystal unit will frequency age about +40 parts per million during the first year. This aging rate is rapid at first but diminishes to almost zero at the end of the year. The same general sort of thing occurs for the dissipation factor, the resistance decreasing to 50 per cent of its initial level and becoming asymptotic within a year. In frequency aging the dispersion is low enough so that the ultimate frequency can be predicted and provided for during final adjustment.

In the early stages of development the fragility of the EDT material gave rise to considerable uncertainty with regard to whether or not the completed units would withstand the shocks encountered during normal handling and shipping. Hence, attention was centered on shock testing and development of suitable plate mounting methods. The photograph of Figure 9 (a single frame from a Fastax camera film travelling at the rate of 8,000 frames per second) shows a crystal rupturing from the indirect impact of a 500-pound weight dropped four feet. A mathematical examination of the displacements observed in a series of these films shows that the crystal plate as now mounted will break at 1,000g but easily withstand 500g. The complete crystal unit, however, will develop a failure of one sort or another such as chips, cracks, or wire attachment failure at about 120g. This compares very favorably with vacuum tubes and shows that the crystals will stand the handling incident to processing and during shipment. Crystals used in telephonic communication networks occasionally are subjected to overload currents when trouble conditions arise. Tests show that the EDT crystals, like equivalent quartz, will handle about 3 milli-

watts of power without injury. Injury in this sense consists of failure of the cemented wire attachment or fracture of the plate itself. It is interesting to note that in the event of crystal plate failure due to overload the successive phases are: surface ionization, heat expansion, then rupture.

In comparing the characteristics of the new EDT synthetic crystal units to the more commonly used cuts of quartz for network applications in the low frequency ranges it may be said that EDT is superior with regard to inductance and ratio of capacities, that it is approximately equal or superior in temperature coefficient, physical size and aging characteristics, but that it is inferior in regard to mechanical strength and dissipation factor.

The Heat Pump From the Utility's Point of View

S. W. ANDREWS
ASSOCIATE AIEE

THE ELECTRIC utility industry is intensely interested in the heat pump because it holds promise of permitting the industry to supply domestic-heating service in an economical manner. Up until now the electric utility industry has supplied very little of this market and we think that without the heat pump we are not likely ever to supply very much of it.

The market, however, is a big one. It has been estimated that the heat required for domestic house heating, if translated into kilowatt-hours of electric energy, would amount to 700 billion, as compared with the total sales of electric energy in the year 1945 to residential customers of 34 billion kilowatt-hours. A market of this size naturally holds out great attractions to our industry if it can be developed in a manner which will be advantageous to the supplying companies, to the manufacturers of equipment, and to the customers themselves.

I should like to discuss with you the matter of the heat pump from three points of view.

1. Why have the electric utilities been unable to serve much of the domestic heating market in years past and why do we say it is unlikely they can ever do so without the heat pump? We think that there are compelling reasons as to why this is the case which I shall try to develop briefly.

2. Why do we think that the heat pump changes the picture and makes it possible for the electric utility industry to go after the domestic heating market? Again there are very compelling reasons as to why this is so, provided that necessary developments can be accomplished to give an economical result.

3. What is the present status of the heat pump? What has been done to date? What further needs to be done? There has been a great deal of publicity in recent months about the heat pump. How close is it to being commercially available?

To date the only available means of heating buildings by electricity is with a resistance-type heater. This may take the form of the small familiar socket appliance with a reflector; a unit built into the wall of a room; an electrically heated steam or hot-water radiator; a panel-type radiant-heating system, or central-heating units which are installed in a duct system supplying an entire building.

In any of these cases, the electric energy is transformed to heat energy by resistance heaters. Any one of these arrangements may be low in first cost from the customer's point of view, but the cost of supplying electric energy to a resistance-type heater used for space heating is high.

If an electric utility company generates most of its energy from fuel, the basic source of heat liberated in the house by a resistance heater is the fuel which is burned in the power plant. Even in the most efficient modern fuel-burning generating stations, we can convert into electric energy only about one-third of the heat energy in the fuel which is burned in the boilers. This does not compare with the fuel-burning efficiencies which can be achieved in the customer's premises. With a modern fuel-burning system, he can achieve a fuel efficiency of 50 to 70 per cent without too much difficulty and thus, from the point of view of fuel efficiency, electric heating with resistance heaters has a basic disadvantage not readily to be overcome.

Regardless of whether the utility company generates its energy from fuel or from water, there is another difficulty in supplying electric heat by space heaters. The annual load factor of heating load is very poor and has been estimated at from 10 to 20 per cent in different parts of the country depending in general on the latitude and, therefore, on the amount of heating service to be supplied. Low load-factor business considered by itself is very costly for an electric utility to furnish because of the heavy fixed charges which have to be met on the facilities necessary to supply the service. It is interesting to note that in the State of Washington, the municipal utilities at Seattle and Tacoma, both supplied largely by hydro energy, recently have found it necessary to institute higher rates for house heating by resistance units than for other types of residential service.

It is our belief that for these reasons electric house heating by space heaters is not likely to be widely attractive to customers, because the customer will probably always have to pay substantially more for the electric service than for some other competitive form of heat, without any comparable advantages to offset the extra cost.

Before answering the second question, perhaps we should describe very briefly what the heat pump is. This has been covered in many articles in the technical press and in various books, and I think it needs just a brief word here.

Basically, the heat pump is an electrically-driven compression-type refrigeration machine. During the heating season it is arranged to take heat from a low temperature source outside the building to be heated, raise the temperature of the heat, and release it in the building. During the cooling cycle the operation of the unit is reversed so that heat can be taken from the building and released outside. This can be accomplished either by reversing the flow of the refrigerant, thus changing the condenser to an evaporator and the evaporator to the condenser, or it can be accomplished by changing the

Paper 48-93, recommended by the AIEE domestic and commercial applications committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 12, 1947; made available for printing December 17, 1947.

S. W. ANDREWS is rate engineer with the American Gas and Electric Service Corporation, New York, N. Y.

flow of the medium, air or water, which is used to carry heat into or out of the building and release it in the house, so that the medium which releases heat in the house by flowing over the condenser during the heating season is redirected to flow over the evaporator during the cooling season.

In considering the heating cycle, heat pumps may be arranged to take heat from the outside atmosphere, from a well, from ground water, from a city water supply, or from the ground itself. Heat may be released in the house in the form of hot air or hot water, but with present types of equipment it may not be released in the form of steam, because temperatures high enough to generate steam cannot be achieved economically on the discharge side of the unit.

Whichever system is used, they each have their advantages and limitations. The important thing to consider is that the unit takes heat already in existence and transfers it from the outside of the house to the inside. It therefore results that the electric energy which drives the machine does not have to supply all or even a major part of the heat which is liberated inside the house. When you compare the amount of heat which is liberated in the house with the heat equivalent of the electric energy used to drive the machine, you have a relationship known as the coefficient of performance. This is always a figure greater than one and it will vary from two, to as high as six or seven, depending upon the temperature of the heat source and the temperature at which heat is liberated. The closer these two temperatures are, the higher the coefficient of performance and, conversely, the greater the difference between them, the lower the coefficient of performance. When these two figures, that is the temperature of the heat source and the temperature at which heat is liberated, vary to a considerable degree, as they will in many installations at different times in the year, the coefficient of performance of the unit will likewise vary.

Let us go back to our discussion of the fuel efficiency involved in the resistance-type heaters. We said that the best efficiency which could be achieved in a modern fuel-burning generating system was about one-third. If we have a heat-pump installation with a coefficient of performance of three to one, which is an average figure that we think can be materially bettered, it results that the overall performance of the heat-pump unit is about equivalent to a fuel efficiency of one. In other words, by taking two-thirds of the heat from the source outside the house and one-third from the electric energy used to drive the machine, we end up by putting into the house just about the same amount of heat which was available in the fuel which we burned in the generating plant to produce the energy necessary to drive the heat pump. Our competitive situation is very materially improved as compared to what it is with the resistance-type heater.

Add to this the fact that the heat pump with a coefficient of performance of three to one takes only one-third as much electric energy and creates an electrical demand only one-third as great as would a resistance heater. This means that the utility company has to supply very much less in the way of generating equipment and transmission and distribution system facilities for the heat pump than for the resistance-type heater; and therefore, fixed charges, the operating costs, and the losses are very much less.

Furthermore, inasmuch as the heat pump can be reversed and can operate to cool a house, it is a unit which operates 12 months in the year instead of just a few months during the heating season. The annual load factor is greatly improved and is perhaps brought up to figures of 25 to 35 per cent in various parts of the country and the cost of energy to be delivered to the customer is thus still further reduced.

Many of us in the electric utility industry, accordingly, think that when suitable heat-pump units are on the market, and when all the various application problems are solved, we will have a tool to use in going after the domestic heating and cooling market, which will put us in a very competitive position and will permit us to serve our proper share of this important market.

Question three was the present status of the heat pump, what has been done and what further needs to be done. Let us discuss briefly these questions from two points of view. The first is the development of equipment. The second is the determination of the best heat source to be used in any installation.

There are a considerable number of heat-pump units in operation both in the United States and in parts of Europe. Up until the time of the war, most of the installations were custom-built. They were mostly installed in buildings larger than residences and they were specially designed and engineered for a particular job. For the most part they took existing component parts and brought them together into workable systems. In the American Gas and Electric System, we have eight such installations, the earliest of which goes back to 1934. These installations are used in office buildings and substations on our system. We have treated each one as very much of an experiment, and have made a variety of tests and kept performance records. Our results heretofore have been widely published.

Since the war, there have been a few manufacturers who have built some units for domestic purposes. These, to a considerable extent, have been simply assembled jobs in which the manufacturer brought together the component parts which he could buy on the market, or some of which he may have made himself. There are not many of them actually in service, perhaps 200 or 300, but they have been treated to some extent as developmental units.

In the spring of 1946, the American Gas and Electric System believed that units could be built which would give better performance and better reliability of service than any which were then available. We accordingly developed, after consultation with many utility companies throughout the country, specifications calling for 3-horsepower single-phase units, single phase because this is ordinarily the only type of electric service available to residential customers. We have invited a number of manufacturers to build units to these specifications and to meet the standards of performance set forth therein. We had in mind that units specially designed and specially engineered for household heating could give high coefficients of performance and could be reasonably trouble free as is the familiar electric refrigerator. Several manufacturers are now working on this problem.

In discussing present status, another phase which I should like to cover briefly is the matter of the determination of the heat source. In many ways you have the simplest installation, and unquestionably the cheapest, from the point of view of first cost, if you take heat from the outside atmosphere. Such a system is especially attractive in latitudes where the outside temperature never goes below, let us say, 30 degrees. The average temperature will be higher than this and the coefficient of performance will be good. An air system has its limitations, however, because the colder it gets outside and the more heat you need to pump into the house, the lower becomes the coefficient of performance and the less the heat output of the machine. A unit taking heat from the outside air, and located in the northern part of the country, might have to be unduly large in size and thus

uneconomic from the first-cost point of view.

A water source of heat has some attractions, but also limitations. If there were ample supplies of ground water and no great difficulties in handling the discharge from the well, this would be attractive because ground water maintains a fairly constant temperature of 40 to 60 degrees throughout the year in many parts of the country. The use of city water would ordinarily be too expensive because of the large quantity which would be required. There are many places in the country where water from any source is not available in the quantities which would be required.

A third source of heat is the ground itself. The ground, like ground water, maintains fairly stable temperatures throughout the country when you get down below frost lines. It would appear that this is the best source of heat for the northern parts of the country and much work is now being done by various groups, within and without the utility industry, on studying this problem to find out how rapidly heat can be taken out of the ground without unduly lowering the ground temperature in the immediate vicinity of the building to be heated and to find out the design and type of equipment best suited for obtaining this heat. The electric utility industry has recently set up a co-ordinating committee with representatives from companies in all parts of the country, as well as representation from both the Edison Electric Institute and Association of Edison Illuminating Companies. This committee has been formed to bring together the results of various research projects and to suggest lines of further research to interested companies and groups.

In closing this short, general summary of the heat pump from the utility's point of view, I should like to express the opinion that the heat pump is definitely beyond the experimental stage, but just as definitely still in the developmental stage. There is a lot of work still to be done before we get to the day when Mr. or Mrs. Customer can walk into a heating contractor's establishment and buy the right kind of unit for his own house with every assurance that it will perform as advertised.

Since we are still in the developmental stages, and no units have yet been built in large quantities with mass production techniques, it is impossible for me to give you any real idea as to what heat pump units for the home are likely to cost. It would seem, however, that the cost of a heat-pump unit should be less than a separate fuel-fired heating system plus a conventional cooling system.

I mentioned earlier that electric rates for house heating by space heaters had been increased recently in the State of Washington. Since we are in the developmental stage with respect to the heat pump, and particularly since we are in a period in which the cost of just about everything we buy is rising, it is likewise impossible to venture a guess as to what ultimate electric rates would be for service to heat pumps. In the case of my own company, and I think this goes for many other utility companies, it is our belief that initially, at least, electric service can be supplied for heat-pump installations under the standard rates available for the customer's regular service. As time goes on and more experience is gained, electric utilities will naturally review the load characteristics of house-heating service and will relate these to the cost of supplying the service. I am sure that electric rates for house-heating service will find their own proper level, just as has been the case in years gone by in the supplying of service to electric ranges, refrigerators, water heaters, and the many other types of load which are supplied by electric service.

No Discussion

Growing Crystals of Ethylene Diamine Tartrate

A. C. WALKER
NONMEMBER AIEE

G. T. KOHMAN
NONMEMBER AIEE

THE NEED for a crystal, preferably one which can be artificially grown, to relieve the critical quartz supply situation has been adequately emphasized in the companion papers by Willis,[1] and Griffin[2] and Pennell. Fortunately this need was foreseen and research activity in the Bell Telephone Laboratories has been intensified over the past ten years* with the objective of finding a satisfactory substitute for quartz for use in circuit elements. More than a hundred materials have been explored in this investigation and the work in this field continues.

Out of this work there emerged, a few years ago, two materials, ethylene diamine tartrate and dipotassium tartrate hemihydrate offering especially valuable promise as piezoelectric circuit elements.[3] Both crystals afford modes of vibration the frequencies of which are substantially independent of temperature and which have attractively high electromechanical coupling coefficients. Ethylene diamine tartrate, referred to hereafter as EDT, was selected for more intensive study as a circuit element because of certain advantages in physical properties. The purpose of this paper is to discuss methods of growing crystals particularly as they are employed in growing large crystals of EDT.

Preliminary measurements to detect piezoelectric properties in crystals are made by methods described by Mason,[4] and for this purpose only small crystals are needed, such as those which spontaneously form when a solution of the salt is saturated at elevated temperature and then cooled to room conditions, or when solvent is evaporated from a saturated solution. For quantitative measurements and for use in experimental apparatus, in accordance with the methods described[1,2] it is necessary to grow crystals of sufficient size so that plates may be obtained of the desired orientation and dimensions.

There are two general methods of growing large clear crystals from solution.[5] These are (1) by gradual reduction of temperature of a solution containing suitable seeds and saturated at elevated temperature, and (2) by feeding a solution saturated at one temperature into a tank containing seed crystals kept at a constant temperature slightly lower than the saturation temperature. In the case of each of these methods flawless growth depends upon supplying salt to the growing face uniformly, which is accomplished by careful control of the degree of supersaturation and by controlled circulation of the supersaturated solution around the growing crystal. The supersaturation is obtained by sensitive and reliable methods of temperature control. Circulation of the growing solution is usually obtained by gentle rocking of a tank[6] in which the seed is planted as shown in the photograph of the rocking tank method, Figure 1, or by the reciprocating motion of a spider to which the crystal seeds are attached in the growing solution as shown in the photograph of the rotary crystallizer,[6] Figure 2.

Paper 48-88, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1948. Manuscript submitted November 13, 1947; made available for printing December 19, 1947.

A. C. WALKER and G. T. KOHMAN are with the Bell Telephone Laboratories, Inc., Murray Hill, N. J.

The rocking tank method which has been successfully applied to the growing of Rochelle salt and ammonium dihydrogen phosphate is not suitable for the growing of crystals of EDT because of a much greater tendency to crystallize from solution spontaneously as compared with the previously mentioned crystals. To avoid interference by spontaneously formed crystals, the rotary method† shown in Figure 2 was developed. Crystal seeds are mounted on a spider rotated with a reciprocating motion through the saturated solution by the motor drive on top of the crystallizer. This motion tends to sweep spurious seeds from the growing faces permitting them to settle on the bottom of the tank where an unsaturated zone is maintained because of the proximity of the tank bottom to the heating element located in the base of the apparatus. A second unsaturated zone is maintained in the top surface layer because water evaporating from the surface condenses on the crystallizer cover as shown, and drips back into the surface layer of the solution. A minimum of circulation in this layer aids in establishing an equilibrium condition of some dilution, thus preventing the spontaneous growth of seeds in this zone.

Although the growing of large crystals is a highly developed industrial process, there is a surprising lack of quantitative information concerning the factors which control crystal growth. It is well known that the presence of traces of certain impurities can distinctly alter crystal habit as shown by the work of W. G. France[7] and as illustrated by the crystals of ammonium dihydrogen phosphate shown in Figure 3. The tapering illustrated by crystal *C* is the result of the presence of 0.001 mole of chromium per liter of solution. As little as 0.0002 mole of chromium produces a detectable effect as shown by crystal *B* as compared with crystal *A* grown from a chromium-free solution.** This effect is probably caused by selective adsorption of ions on

* The survey of materials and the growth of the initial crystals for research investigations has been in the hands of A. N. Holden. Crystallographic aspects of the problem have been handled by W. L. Bond, and the electrical and elastic measurements and their interpretation by W. P. Mason.

† Developed by A. N. Holden.

** The effect of chromium on the growth of ammonium dihydrogen phosphate was first observed by H. Jaffe of the Brush Development Company.

Figure 2 (above). The rotary crystallizer

certain crystal faces which alters their relative growth rates.

Viscosity is an extremely important factor in crystal growth as illustrated by the devitrification of glass, which term is used to describe the very slow conversion of this supercooled, highly viscous liquid into a crystalline solid. In contrast, the rate of growth of crystals is very fast from an aqueous salt solution, even one of relatively high viscosity such as ethylene diamine tartrate. Because of the intimate and complicated relationship between temperature, solubility and viscosity, it is difficult to predict the influence of temperature on rate of crystal growth. Temperature controls both solubility and viscosity but since viscosity normally decreases with temperature and increases with solubility there are two opposing influences on crystal growth. As a result rate of crystal growth may pass through a maximum with increasing temperature. One of the common methods of altering crystal habit is by control of hydrogen-ion concentration. This effect is of great value in controlling tapering effects. The effect of degree of supersaturation has been studied by H. E. Buckley[8] who found that new faces can be made to appear and disappear by varying this factor. This effect is evidence of a different rate dependence on supersaturation for the various crystal faces.

The first step in the growing of EDT crystals is the preparation of the salt, which until recently was only a laboratory curiosity. The salt was first prepared by Colson in France in 1892,[9] but sizable quantities of it were first prepared in the Bell Telephone Laboratories in 1945 for use in growing large EDT crystals weighing approximately one pound each. The salt is prepared by adding solid crystalline tartaric acid to a solution of ethylene

diamine in water. Because considerable heat is evolved on mixing the acid and the basic ethylene diamine it is necessary to provide cooling during this operation. Despite this some slight decomposition occurs and the mixture is colored more or less depending upon the effectiveness of the cooling. Most of this decomposed brownish colored material may be removed by stirring with decolorizing charcoal and filtering. The salt is next separated in the form of masses of crystals such as those shown in Figure 4, number 1, by preparing a solution of the salt saturated at some elevated temperature and allowing to stand in a cool place for some days. The larger and better formed crystals in such a mass are selected as seeds and planted in a solution saturated at some fixed temperature between 40 and 50 degrees centigrade. Saturation is accomplished by vigorously stirring the solution at this fixed temperature in the presence of an excess of finely divided salt for a period of approximately ten hours. The excess solid salt is then allowed to settle and the clear liquid pumped off. This solution is heated above the saturation point to insure complete solution of chance crystals. In the absence of such nuclei it is possible to supercool a solution of EDT salt by as much as 10 degrees centigrade, without danger of crystallization. It is this property of supercooling which makes it possible to grow large crystals from solution.

Seeds planted in a supercooled solution will grow at a rate dependent upon the amount of such supercooling (supersaturation), temperature, and circulation. At extreme supersaturation, growth becomes uneven and veils occur, or spurious seeds form and are adsorbed on crystal faces where circulation is poorest, inducing abnormal growths at such points. It is an interesting fact that crystals containing imperfections or abnormalities grow more rapidly than perfect crystals, and crystal growth thus bears some resemblance to the physiological growth of cancerous tissue.

Under optimum growing conditions growth takes place almost entirely on the two natural faces which compose the wedge-shaped left end of the crystal in

Figure 6. Inserting spider in growing tank

Figure 7. Schematic of constant temperature crystallizer

Figure 4, number 3. Thus small perfect seeds will grow into long needle-like crystals with cross sections very little larger than those of the original seeds. The abnormalities resulting from adsorption of spurious seeds on nongrowing faces is of great advantage in providing a means of enlarging the crystal cross section, an otherwise slow and tedious process.

The fastidious nature of crystals is well illustrated by their reluctance to grow clear material on faces other than the natural ones.* An artificial face, even when off angle by only a fraction of a degree must first be covered with faulty, veiled growth until the plane of the natural face is reached. This accounts for the cloudy (veiled) portion observed in the initial growth section of EDT crystals formed from a cut section, and is the reason for the fact that the growing process involves two operations. These are: (1) capping—the formation of the natural faces or caps on a cut plate of the proper cross-section; and (2) bar growth—the formation of clear material on the seed cap cut from the wedge-shaped end of a capped seed plate. In Figure 4, number 2 is such a seed plate, number 5 a capped seed plate, and number 3 the useful growing end of the capped seed plate which forms the seed for growing the final bar, number 4.

Plate seeds are usually cut thick enough to permit the drilling of mounting holes, arranged so that the plates may be mounted on the spider shown in Figure 5, and oriented for solution flow across the major cut surfaces. Growth takes place on both these cut surfaces, accompanied by marked veiling, until all of the natural faces are formed on each side. Such capped seed plates are then harvested and the wedge end containing the two growing faces is cut off, drilled for mounting on the spider in Figure 5 in such a way that the solution flow is against these growing faces.† A spider, fully mounted with these caps is being lowered into the growing tank in Figure 6. When in place, the tank is equipped for operation and placed in a room heated to about 50 degrees centigrade. Solution saturated at 45 degrees centigrade, is pumped into the tank at a temperature four to five degrees above the saturation point. The filled tank is then held at this temperature for several hours with agitation of the spider to dissolve any crystal fragments adhering to the crystal faces, and when the growing surfaces of the crystals are quite clean of misoriented material the temperature of the room is brought to 25 degrees centigrade, and that of the solution is slowly dropped over a period of several

* The usual natural faces on EDT crystals are those forming the four prism sides of the bar, the two faces forming the wedge-like tip on the clear end of the bar (the growing end), and the faces comprising the opposite end along the growing or Y-axis. This latter end does not grow appreciably after the natural faces are formed, and these faces may appear either as a wedge (see right end of the bar crystal number 4 in Figure 4), or as four faces converging to a pyramid (see the beginning of this pyramid on the right end of the capped seed plate number 5, Figure 4). Other faces sometimes appear, depending upon impurities, but little is known as yet regarding this aspect of the EDT crystal habit.

† Once sufficient numbers of good bars are available the clear cap ends are cut off and used as seeds for growing more bars, and the capping operation is no longer necessary.

hours until growing commences. After this the solution is cooled a few tenths of a degree per day, which causes the crystals to grow approximately one inch per month along the growing direction. During the early part of this growing period the cut face of the wedge fills out to the natural, nongrowing faces, and thereafter substantially no growth takes place on these wedge or pyramid faces.

For large scale production, a constant temperature method has a number of important advantages. The control of temperature at a fixed point does not require the complicated programming controls needed in connection with the dropping temperature process. Growth rates are also under better control and the total amount of growth obtainable is not dependent upon the quantity of salt contained initially in the solution, as will become clear later.

For pilot plant production the constant temperature apparatus, shown schematically in Figure 7, was constructed and is shown in Figure 8. The unit consists of three interconnected tanks, *A*, *B*, and *C*, see Figure 7, each provided with separate, relatively simple temperature controls. Seeds are mounted as previously described on a spider in *C*, and the system filled with saturated salt solution. Excess salt is added, as needed, in granular form to tank *A*, and this is kept thoroughly mixed with the solution in this tank by means of an efficient stirrer. The temperature of tank *C* is held at the growing value, that of tank *A* at a slightly higher temperature, and because of the presence of solid salt in this tank, this temperature is the saturation point. Tank *B*, termed the superheater, is kept at a still higher temperature than *A* to prevent the formation of spontaneous seeds in the solution pumped into the bottom of *C* by means of the pump *D* in tank *B*. As this heated solution flows into the bottom of *C* it quickly cools to the growing temperature as it rises in the tank and the excess salt corresponding to the difference in solubilities at the temperatures in tanks *A* and *C*, supplies the material for crystal growth. The overflow from tank *C*, from which much of this excess salt has been removed by the growth of the crystals, returns again to tank *A* where it is resaturated at the higher temperature.

Solution flows from tank *A* into *B* by gravity, through a filter *E*, which removes suspended crystals. The superheater tank *B* insures that any crystalline material passing through the filter will be dissolved before it reaches the pump. This cycle can be continued as long as there is room for the crystals to grow in *C*, by adding salt to the saturator tank *A* as required. This system is extremely flexible as it readily permits adjustments of temperature, rates of flow, and solution composition during the course of a run.

Figure 8. Constant temperature crystallizer

It is desirable to grow EDT crystals at a temperature just above 40 degrees centigrade. As heat currently added to the solution in the tanks during the growing process must be dissipated, the entire apparatus is enclosed in a space provided with some refrigeration and temperature control. In harvesting the crop of crystals the temperature of this space is brought to ambient and the solution pumped from the tanks to storage containers. The crystals are then allowed to remain undisturbed for a period of from 24 to 48 hours before they are removed from the spider. This permits temperature equalization and drainage of solution from the crystal surfaces. Also there is some evidence that an annealing action may be involved. The crystals are then removed, allowed to drain on dry cloth covered tables to remove solution trapped in the porous area within the veiled central section. Finally they are placed in individual cellophane bags to protect them from mechanical and thermal shock while being transported for processing by methods described by Griffin and Pennell.[2]

In addition to the electrical characteristics described by Mason,[5,6] EDT crystals possess certain peculiar growing habits. As noted previously for reasons not understood, EDT grows only in one direction under the conditions here described. Therefore, when a plate is cut from a bar some means must be provided for identifying the surfaces on which form the growing and nongrowing cap faces, so that when mounted on the spider, interference will not occur during growth.

A second and troublesome characteristic of this crystal is its tendency to crack. There are large temperature coefficients of expansion in the crystal and when the temperature of the surface of the crystal is suddenly changed from that of the main body, cracks are likely to occur. This tendency necessitates the use of special cutting techniques described by Griffin and Pennell.[2]

A third characteristic is the tendency for new faces to appear or disappear during growth, probably resulting from some changes in growing conditions, such as hydrogen-ion concentration and the introduction of impurities from a variety of sources.

The pilot plant stage in the growing process previously described has been of great value in the development of the manufacturing process. It has been possible to increase growing capacity by the use of as many as six growing tanks coupled to each saturator and superheater unit. The knowledge gained through operation of the pilot plant has made it possible to foresee difficulties in produc-

tion and to trace causes of faulty growth in time to prevent serious loss of time and material. The capacity of the Western Electric plant to produce EDT crystals for use as a quartz substitute is expected to go far in reducing the shortage of natural quartz, especially of the larger sizes required for filter applications. Improvements are in progress which should approximately double the percentage of usable material per pound of crystal as compared with that for natural quartz. It is therefore expected that in addition to conserving quartz for military and other applications this development will provide a reliable domestic source of supply of crystals for long distance carrier telephone systems.

Discussion

W. L. Casper (Bell Telephone Laboratories, Incorporated, New York, N. Y.): The development of synthetic crystals was undertaken because of a shortage of quartz crystals suitable for use in carrier systems. The situation before the War had given no indication that crystals could not be obtained in any quantity that might be needed for the expansion of the telephone plant. The War caused both a complete dislocation in supply and demand and an unprecedented need for additional telephone service.

Crystal units used in carrier systems, in general, operate at frequencies from 4 to 150 kilocycles. Many of them have large plates compared with those operating at radio frequencies and must be cut from relatively large crystals. They are used for the following four purposes requiring progressively larger amounts of quartz:

1. Generation of the basic frequency from which the carrier frequencies are derived.

2. Selection from the basic frequency of the harmonics required for the carriers.

3. Picking off of certain frequencies from the line which are used in the regulation of the circuit.

4. Separation of speech or program channels, or groups of channels.

Quartz not only simplifies the regulation problem of carrier systems, but enables very efficient use to be made of the frequency spectrum available in providing a large number of channels each giving a high grade of telephone quality.

Quartz for these units is obtained from Brazil and before the War the 5,000 to 7,000 pounds needed annually were easily procured. A stockpile large enough to last several years was maintained to guard against periods when the supply might possibly be shut off. Japan imported large quantities of the smaller crystals for use in the manufacture of cheap jewelry. As only a few per cent of the quartz crystals mined were large enough for carrier circuit crystals, the sales to Japan were an important factor in enabling the mines to operate.

When the War came along the Armed Forces decided to use quartz for radio oscillators to obtain ease of handling and maximum reliability of the radio transmission. Many radio sets required 100 crystal units or more per set, and the demand skyrocketed. The Government instituted an extensive program to obtain the needed quartz from Brazil, and more than 100 shops were set up to manufacture quartz units. While most needs of the Army Forces could be taken care of by the smaller quartz crystals—too small for the lower frequency carrier crystal units—many manufacturers preferred to cut the larger quartz crystals and many were used in this way. Some War projects also required even larger quartz plates than are used in carrier circuits.

During the War only such carrier systems were manufactured and installed as were essential to the War effort. All procurement was under priority control. The quartz required for this production was allocated by the Government. Stockpiling by the Bell Telephone System for future telephone business was out of the question, although it was increasingly evident as the War progressed that a large demand for telephone service was building up.

The end of the War left the telephone companies with a large number of potential customers asking for telephone service. To give them this service, it was not only necessary to provide them with station sets for their homes, but also to add to central office equipment to handle the increased traffic and to add substantially to the long distance plant. To meet this demand for service, it was necessary to increase production of long haul carrier systems to ten times what it had been before the War.

While at V-J Day there was a sizeable supply of quartz crystals in the country, these were mainly small crystals, and the available supply of large crystals was wholly inadequate. Japan was no longer in a position to import the smaller crystals nor was it necessary for the Armed Forces to continue their purchases for War purposes. With practically no demand for the smaller crystals, it looked extremely doubtful whether mining for the larger size alone would be sufficiently profitable for operations to continue. The expectation of obtaining the quantity needed was decidedly bleak.

Fortunately, a research program on piezoelectric crystals had been in progress for a considerable period. The crystals of all known minerals which had any possibility of being useful had been investigated and the program had been extended into the synthetic field. These studies had produced two possible synthetic crystals. Of these, ethylene diamine tartrate (EDT) was chosen as giving most promise.

It was not only necessary to develop methods of growing this crystal in quantity, but crystal units had to be designed. This crystal has very different physical characteristics from quartz and many of the methods of fabrication that were used with quartz had to be modified for use with this material.

In order to get in production before the available quartz was used up, the development of methods of growing and of fabrication of the units was carried on simultaneously with the design and the working out of the manufacturing methods and the tools needed for quantity production. In some cases tools were designed and ready for use before the manufacturing process which required them had been proved satisfactory in the laboratory.

At the present time EDT crystals are being produced commercially. Many preproduction filters containing EDT units have been shipped to the field and are giving satisfactory service in different parts of the country. Commercial production has started on both EDT crystal units and the filters which contain them.

Owing to the success of this development program and to improvements in manufacturing yield in the use of quartz, all the crystal filters needed for extension of the long distance circuits will be produced.

The demand for large quartz crystals has been reduced to the point where the difficulty of a foreign source of supply should no longer be troublesome.

Precise Turbine Governor

HENRY E. WARREN
ASSOCIATE AIEE

AN IMPORTANT IMPROVEMENT in the art of regulating water or steam turbines has been made possible by the development, during the past two years, of a very precise governor.

The prime movers in all generating stations are provided with governors, nominally for the purpose of controlling the speed of the prime movers and consequently the frequency of the generators. These governors do in fact control speed until the generators are connected in parallel with other generators on a system. Thereafter they control primarily the load distribution among the machines.

Governors are almost all very similar in principle of operation and, generally speaking, in performance. Most of them are considered satisfactory because they behave well when controlling units on large systems. This apparently satisfactory service results because the function of these governors is then little more than to hold the gates of their turbines in substantially fixed positions, except when they are adjusted by hand or by auxiliary devices to reduce or increase the output of their units. They are always ready to respond to large speed changes but these large speed changes almost never occur except from accidental trouble. Actually the governors may be considered almost equivalent to safety devices which prevent runaway upon sudden loss of load.

Conventional Governors

The essential elements of a conventional governor are shown in Figure 1. This type of machine may be described briefly as follows:

A powerful hydraulic motor or "servomotor" attaches to the gates of the turbine prime-mover. This servomotor operates on the hydraulic energy of a liquid, stored in a tank under a pressure of several hundred pounds. It is very accurately controlled by a combination of valves which normally includes two units. One of these units is quite large and the other comparatively small and easily displaced by relatively slight force. As indicated in Figure 1 the smaller valve so controls the hydraulic energy supply as to make the larger one track all its own movements, but with vastly greater capacity and with negligible reaction on whatever mechanism initially operates the smaller valve. In effect, the two valves may be looked upon as one valve which combines ample capacity to operate the largest servomotor with insignificant opposition to its own displacement.

This resultant valve, whose operating point is that marked A in Figures 1 and 2, is itself under the control of four distinct elements. The first of these is a speed-sensitive device or tachometer, generally consisting of revolving weights free to move radially against the opposition of a spring; the second is the driven end of a dashpot whose driving end is connected to the gates of the turbine; the third is also a connection to the turbine gates, but without dashpot; the fourth is a member moved by a motor under control of the switchboard operator.

The utility of this construction may be explained most clearly by considering two typical cycles of operation. Suppose first that the generator attached to the turbine in question is not connected to any other generator. Then any decrease in its load leads to an increase in its speed, which in turn causes the tachometer stem to drop, and the valve to open in such direction as to close the turbine gates; these in closing act through the dashpot and to a much smaller extent through the other element operated by the gates to close the valve; the valve is thus closed before the tachometer itself returns to the position from which it started; this results in stable operation, but it also results in a change of that tachometer stem position which corresponds to the closed position of the valve; this change is such that now the speed is slightly higher than it was originally, although far less so than if there had been no governor. This is a manifestation of what is called "speed droop." Because of the dashpot, the effect of the gate motion on the valve can be large at the beginning of a governing cycle and thereafter decrease gradually and automatically as the cycle proceeds. Thus the ultimate change in speed because of a change in load would be nonexistent were the dashpot-equipped connection the only one between the gates and the valve operating point. This, however, is not permissible in the case of a unit which is to operate in parallel with other units, since isochronous alternators offer no means of controlling the division of load among themselves; hence the inclusion of a rigid supplementary connection from the gates back to the valves. Obviously, the effect of this connection can be undone by the motor driving the fourth element; this motor may be manually started and stopped, or may be made responsive to a variety of automatic devices.

In the second case, consider the generator connected with other generators on a large system, the steady state frequency of which is determined by some other governor or governors. There is only one position of the gates at which the governor valves remain closed, since the speed is fixed, fixing the tachometer stem position, and the gates are rigidly linked to the valves through the supplementary connection. The only means of changing the gate position is the motor of the fourth element. Thus, for an externally fixed system frequency, this motor becomes a

Paper 48-90, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 10, 1947; made available for printing December 22, 1947.

Figure 1. Schematic diagram of conventional governor mechanism

Figure 2. Schematic diagram of new governor mechanism and connections

load control device, and the entire governor is a load governor rather than a speed governor. Of course, should the generator become separated from the fixed-frequency system, the governor would instantly resume its function of speed control, and return the speed of its unit to whatever value the position of the "load control" motor at that instant called for.

The New Governor

The new governor mechanism is shown schematically in Figure 2; Figure 3 illustrates a demonstration governor of the new construction. Aside from the fact that a liquid-type tachometer is substituted for the fly-ball form shown in Figure 1, the principal difference between the new governor mechanism and that of the conventional governor is that the place of the dashpot is taken by a selsyn motor of a standard type. This forms the terminating element of an electromechanical device that performs the oil-dashpot function just described with greatly improved precision and reliability. In addition it replaces the load control motor and offers possibilities of accurate load and speed control not heretofore attainable directly.

Thus the dashpot with its necessary oil, which has always been troublesome, is completely eliminated. There remains in this new governor a simple speed measuring device, preferably a metal bellows opposed by a spring and supplied by liquid from a centrifugal pump directly driven by the turbine or by a synchronous motor. However, any standard form of governor tachometer having spring opposed centrifugal weights may be used equally well. The function of the tachometer, as in the conventional governor just described, is to operate the valves so as to maintain approximately constant speed on the unit.

The electromechanical system of which the selsyn receiver incorporated in the governor forms the last element is shown diagrammatically in the upper part of Figure 2. It consists of a pair of synchronous motors jointly operating a mechanical differential which in turn operates the transmitter end of the selsyn combination. A simple clutch and handwheel are provided so that the station operator may operate the turbine gates directly from his switchboard; this is a quick way of resetting the load on a unit, and, since the handwheel is easily provided with an approximate gate-opening scale, it is preferable to the tentative and unprecise scheme of push-buttons conventionally used to operate the "load-control" motor of Figure 1.

One of the two synchronous motors which operate the selsyn transmitter is permanently connected to the generator under control; the other may be connected either to the system bus, or to a suitable source of reference frequency. With the first mentioned connection, there is provided a means of exact adjustment of the speed to its desired value as measured by the system frequency. The unit, even when started from rest, will come up very quickly and stably to full and exact system speed. It will remain at this speed indefinitely, duplicating of course all minor changes in the system speed, but always ready to be connected to the system. Thus the problem of putting a new unit on the line is considerably facilitated. After the unit has been connected to the system by this method the two synchronous control motors will always run at exactly the same speed, therefore the turbine output will remain wherever it may be set. Under these conditions the unit will not tend to correct the system frequency.

If the supply to one of the synchronous control motors is now shifted to the reference frequency the unit will immediately try to correct the system frequency to correspond with that of the frequency

standard. If the system is in error the output of this unit will increase or decrease in such sense as to correct the error. It will be noted however, that all governors of this type, wherever they may be located on the same system, always act harmoniously; that is, each begins to respond to a minute frequency deviation at the same instant and in the same direction, since they are all measuring frequency against a high precision standard instead of being limited in this respect by mechanical features as are the present governors.

Consequently the use of governors of this type will tend to eliminate one of the difficulties now commonly encountered, the unco-ordinated absorption of load changes by machines whose governors behave erratically within and at the edges of their "dead bands." It is obvious from the foregoing that this governor cannot have a dead band, either as to speed or as to load, because it necessarily continues to act until the speed it is controlling matches the reference speed. The manner in which the equivalent as regards load comes about will appear in what follows. This is advantageous in that unnecessary changes in frequency and gate position are reduced. A differential selsyn could be used instead of a pair of synchronous motors with mechanical differential.

Problems of System Regulation

Modern power systems are so large that the problem of maintaining frequency as such no longer occupies a prominent place in practical system regulation. Of the load changes normally experienced nowadays, the more rapidly occurring ones are sufficiently small, relative to the stored energy in the system, and average sufficiently near zero, to cancel out and leave only a drift to be corrected. There could hardly be a form of frequency change better suited to correction by governors of this new kind. It is perhaps not unfair to say that the exact opposite is true for conventional governors, since these measure speed, not in terms of speed itself, but rather in terms of the position of a group of levers subject to friction errors. However, the same system expansion which minimized the immediate frequency problem has introduced others; for example, it is no longer feasible to entrust the final supplementary regulation to one station whose governors are equipped with master clocks; neither tie-line capacity nor reserve requirements could permit this procedure with a large modern system.

The solution to date has been the addition of more and more complicated supplementary devices to the governing apparatus; the overwhelming majority of them operating through the load control motor of the fundamental governor. When the delays and irregularities inherent in this method are considered, the extent to which it functions satisfactorily seems remarkable.

Figure 4 illustrates the behavior of a large modern system as regards frequency. The chart was made by means of a synchronous motor-differential recorder very similar to the frequency comparing mechanism shown in Figure 2; this yielded the integral of the frequency deviation, curve *A*. This curve was differentiated graphically to obtain the frequency, curve *B*. From the fact that the frequency changes but slowly, and shows no marked short period irregularities, it seems clear that the major burden of system regulation is borne by the precise supplementary regulators.

The first supplementary devices applied to governors were master clocks; much of the final regulation imposed today remains based on clocks of one kind or another. It is of course true that time keeping is one of the services supplied by power companies, and that the income they derive from it is far from negligible. This does not mean that all regulation must be subordinated to time service, and the more recent regulating systems are largely based on actual frequency for all short period operations, and return to timekeeping only over much longer intervals. From the viewpoint of actual system operation, the principal virtue of accurate frequency regulation is that it facilitates proper tie-line loading and economic load distribution. This does not change the fact that the most sensitive measure of frequency, with simple apparatus not requiring elaborate energy amplification, shares with timekeeping the quality of being a measure of integrated frequency. This is the sort of apparatus used in this governor, but here the interval over which the integrating process is conducted before the resulting measure of frequency is applied to the governor is reduced to zero.

Furthermore, the short period reference frequency used is not necessarily the frequency of the earth rotating about its axis, as it is in timekeeping, but is instead an approximation to it readily modified by such things as tie-line wattmeters or other devices, Figure 2. It is possible, by means of this direct, powerful, and rapidly acting measuring device forming a part of the governor itself, to eliminate the complicated conventional combination of an insensitive, imprecise, and somewhat unpredictable governor with a sensitive, but complex and indifferently well articulated supplementary regulator.

Figure 3. A demonstration governor of the new type

Figure 4. Frequency deviation on a large system and its integral

The Reference Frequency

The source of reference frequency employed in the governor is a modified form of the vibrating wire standard used for telescope control on Mount Palomar. This latter device was described in a paper published in 1939.[1] In such instruments the rate of vibration of a tension member supporting a relatively heavy mass is determined sharply by the total force exerted by the mass. Since a portion of this mass is a large circular Alnico magnet having a coil of wire located in its air gap, the gravity force can be increased or diminished by an attraction or repulsion force between the magnet and a small current passing through the coil. The amount of this current is accurately controlled by the potentiometers shown in Figure 2 at several points.

One of these potentiometers, being operated mechanically by the gates of the turbine, tends to decrease the reference frequency as the gate opening increases. This is equivalent to the conventional speed droop, and its magnitude is readily controlled by the setting of the shunt across the coil. The manually operated potentiometer at the switchboard determines the gate opening at which the reference frequency matches the system frequency when the latter is normal; this means that the potentiometer sets the normal load carried by the unit. The unit's deviation from this normal load constitutes its contribution to the regulation of the system, and can be made either large or small as desired by resetting the shunt.

The operator also has, through the simple friction clutch and handwheel described before, direct control over the selsyn motor which takes the place of the dashpot. Therefore he can almost instantly open or close the water wheel gates to any desired extent in a very definite way. As before mentioned an indicator on the selsyn generator at the switchboard shows on a scale the approximate gate position at all times.

Conclusion and Summary

The very complicated problem of load and frequency control over great systems will obviously not be solved completely by the substitution of this kind of governor. Economic generating requirements, reserve power needs, and tie-line loading must have human attention. It is the writer's opinion that operating difficulties will be lessened in proportion as the governors are made more sensitive to the frequency, so that they may all act consistently.

It seems probable that if enough units on a large system could respond immediately to extremely small deviations from exact standard frequency, the change in power output for each unit would be so small as to be almost negligible and the load dispatchers would need only to add and subtract blocks of power from time to time to conform with the relatively predictable large load variations. There would of course remain the problem of tie-line interchange between large areas. This would require, as at present, governor biasing on certain units, which can be done with a special ease and precision on the new form of governor. The new governor does not involve any radical changes in the general method of moving the gates or valves of a turbine. There is much to be said in its favor on account of the elimination of any dashpot. The cost of installation should compare favorably with that of the present type of machines, and should be appreciably less where governors must be equipped with precision auxiliaries.

Summary of Methods and Results Characteristic of New Governor

1. Speed measured approximately by a conventional type of tachometer, with ample speed droop for stability.

2. Precise speed adjustment superposed on approximate speed adjustment by comparing frequency of unit with a reference frequency. This comparison is made by a differential coupling between two synchronous motors or by a differential selsyn. In this manner the need for a dashpot is eliminated with benefit to stability and precision.

3. Provision for direct tie-line load and other control incorporated in governor.

4. Elimination of dead band of governor, and uniform behavior of all governors of this kind on a system.

5. Governor control and frequency comparison instruments located at switchboard. Operator can make definite adjustment of load.

6. Complete control at switchboard of the governor's contribution to system regulation.

7. Reduction of time required to bring unit from rest to exact system speed.

Discussion

W. M. Pickslay (Pacific Gas and Electric Company, San Francisco, Cal.): From the system aspect, it would appear that the performance of this governor is exactly the same as that of the present more conventional governor with one important exception. That is, both governors are characterized by a drooping speed-load or gate opening curve, but the author's governor, at least for small frequency deviations, is sensitive to the integrated frequency deviation rather than the instantaneous frequency.

Because of this difference, there is no direct means of measuring the exact improvement in preciseness that can be realized. However, a fair idea of the relative improvement would be secured by comparison of the exact frequency and integrated frequency deviations which will cause motion of the gates. In a good modern conventional governor, a frequency deviation of 0.006 cycle (2.16 degrees per second) may be expected to initiate corrective action. While Warren speaks of elimination of "dead band," it is from the point of view of the new governor's continuing to act until there is an exact match between controlled and reference frequencies. Owing to friction load on the selsyns together with their normal positioning error of 1 to 2 degrees, there must be some finite value of integrated frequency deviation required to take place before gate motion will result. The magnitude of this is required for the comparison.

The improvement realized must be evaluated further from another point of view. During system frequency changes, the sooner the gates are moved, particularly on units nearest the load change, the less will be the excess gate opening or kilowatt generation required to prevent further deviation and to restore the frequency to normal. On the other hand this results in more frequent governing. Experience will be required to determine whether or not it will result in excessive maintenance of governor, valves, and gate mechanisms.

The author assumes that frequency deviations occur simultaneously throughout the system. This is implicit in the statement to the effect that all the new type governors begin to respond at the same instant. Actually, a frequency deviation due to a load change at one point in a system will be some time in showing up at a remoter point since an angular difference between ends of transmission links must appear before the transmitted power can be altered to produce a change in frequency at the farther end.

While increased sensitivity may be expected to reduce the magnitude of tie line power swings, supplementary control is still necessary for steady state control of power interchange beyond that afforded by droop settings. If, however, the reference frequencies of all units so governed were synchronized with zero droop, it is probable that supplementary control could be eliminated and increased maintenance justified. An approach to this has been previously

Figure 1

proposed[1] which not only should result in improved control of individual and interchange power but also contribute directly to system stability during fault or emergency conditions.

REFERENCE

1. POWER SYSTEM GOVERNING, T. E. Curtis. ELECTRICAL ENGINEERING, December 1947, pages 1197–1200.

J. E. Allen (Pennsylvania Water and Power Co., Baltimore, Md.) and **W. B. Hess** (Safe Harbor Water Power Corp., Safe Harbor, Pa.): The author is to be commended for his pioneering efforts to find a new solution to the problem of turbine governing. The system which he describes has several novel features such as the frequency standard with means for introducing speed droop by shunting coils, the differential method of comparing the turbine speed with a reference standard, and elimination of the dashpot.

It is noted that the author refers to his governor as being a precise one and that it has no dead band. However, no performance data have been given to show whether or not this characteristic has been realized in practice. If there is no dead band it would be expected that a card diagram of frequency versus gate opening with the turbine governor regulating would be a line with slope corresponding to the inherent speed droop. This ideal has never been fully realized in existing governors but excellent performance approaching this ideal, especially for steam governors, has been disclosed in publications.[1,2] In the discussion to reference 1, and in reference 2, test records are shown of very sensitive steam governors having card diagrams resembling straight lines. Under the same discussion an instance is also shown of a governor for a large hydraulic turbine which is considered excellent for a governor having a compensating dashpot. Progress made in instrumentation now permits the obtaining of card diagrams of frequency versus gate opening while the governor is regulating on the system. It would be desirable, therefore, to present such performance records of the precise turbine governor to show how much the art has progressed. It would be especially interesting to see the record of performance of this governor when applied to a hydro unit.

It is not clear when the author refers to the governor having no dead band whether it is meant to include the pilot and main valves. In accordance with Joint AIEE-ASME* Committee on Recommended Specification for Prime Mover Speed Governing, dead band refers to the relationship of the turbine operating piston with respect to a given speed change. Pilot and relay valves usually have a certain amount of lap which would introduce some dead band. It would be helpful if the author would clarify his definition of dead band.

The speed droop is obtained by shunting the coils of a frequency standard energized from a d-c supply. It is obvious that the source of d-c would have to be stable; otherwise, it would affect the governor performance. It would be interesting to know just what degree of stability is required for the d-c voltage supply.

The author comments on the deficiencies of existing governors. In some instances his comments are well founded. However, improved performance can frequently be obtained by proper adjustments and adequate maintenance. Instruments are necessary to accurately and readily measure the performance characteristics and to evaluate the results of corrective measures.

2. A TURBINE-GOVERNOR PERFORMANCE ANALYZER, Discussion, R. Sheppard, C. Concordia. AIEE TRANSACTIONS, volume 61, 1942, pages 393–4.

C. L. Avery (Woodward Governor Co., Rockford, Ill.): Figure 1 is incomplete in that a by-pass needle valve should be shown in the dashpot. The operation of a conventional governor is then more correctly described:

"Because of the dashpot by-pass, the effect of the gate motion on the valve can be large at the beginning of a governing cycle and thereafter decrease gradually and automatically as the cycle proceeds."

Functionally the system shown in Figure 2 continuously corrects the speed level setting of the governor mechanism through a speed matcher. Continuous correction appears to be an improvement over the impulse corrections in common use. There is nothing new and different about speed matching. The speed matcher is an established device. Speed matchers of a more direct acting type have been used for over twenty years. The novelty of this system lies in the control system which actuates the speed matcher. If this system has any practicable advantage over the supplementary regulators presently available, it can be applied to existing governors without difficulty.

With reference to hydraulic turbine applications, when the dashpot is eliminated, some other means of stabilizing the unit must be provided. This is accomplished in this type of control by imposing permanent speed droop on the "tachometer." For medium head wheels with fairly long penstocks, stabilized by droop alone, values in the neighborhood of twenty per cent or higher are required. It would be interesting to know whether this governor has been applied to turbines of this type.

Presently available modern governors respond to very small speed changes. (Smaller, in fact, than can be detected by commercially available frequency meters.) They respond and continuously correct the loading on the controlled units as dictated by the speed droops to which they are adjusted. For the sake of simplicity of explanation, it is a common fallacy in discussing governors to assume that a large system operates at constant frequency. No generating system ever operates at a constant frequency for long. Therefore it is important for a governor operating on a large system to follow the frequency, and accordingly correct the load on its connected unit as faithfully as possible in order not to be entirely out of step with the instantaneous demand of the system. The time lag between the cause and effect should be held to a minimum.

Figure 4 shows time lags in the order of ten minutes between the frequency line *B*, which is the indication of load demand and the integral of the frequency deviation line *A*, which is the indication of load requirement as received by the governor mechanism shown in Figure 2. Furthermore, Figure 4, which shows the trend of average frequency, does not give a typical picture of the instantaneous frequency variation on a power system. Figure 1 of the discussion for instance, taken on a large system, using a high speed, highly sensitive frequency meter shows that frequency actually fluctuates much more violently than would be expected from Figure 4.

Lacking performance data, it is not possible to discuss the performance of the control system described by Warren. An analysis of such data when it is made available should not disregard the above mentioned requirement for good control on central systems.

Henry E. Warren: In answer to the discussion by Allen and Hess, I would say that the reason why the ordinary kind of turbine governor has a dead band while the new Warren precise governor does not have a dead band is as follows:

In the conventional type of governor the entire sequence of motion depends primarily upon the measurement of speed by balancing the centrifugal force developed by revolving weights against a spring. This balancing is obtained by the use of parts which include bearings, pivots, and collars. All of these have slight friction. Since there is friction the equilibrium position for any given speed is slightly indefinite and this indefiniteness is responsible for part of the so called dead band. In addition, however, there is usually a slight amount of lap either negative or positive in the valve connected with the speed measuring element and there may be some end play in the connecting parts.

The sum of all these factors accounts for the dead band which may be considered as the minimum amount of speed change required for a positive movement in one direction or the other of the servo-motor piston. This definition corresponds with that of the recommended specifications of the ASME and AIEE. This is a static phenomenon and the failure of any response

* American Society of Mechanical Engineers.

to a slight error in speed may continue indefinitely. Such a dead band as this probably can never be entirely eliminated although it may be made very small.

The Warren governor does not depend upon a device which attempts to measure the exact value of the speed or frequency directly but in place of that there is comparison mechanism that determines the difference in motion between two revolving elements. One of these elements represents a standard speed or frequency and the other one the speed or frequency of the unit under control. Since both of these revolving elements are in constant motion and friction is not involved, there cannot be the slightest difference in speed without producing a differential resultant motion. This resultant motion is bound to continue as long as there is any difference in speed. Since this resultant motion brings about displacement of a valve and the movement of a servo-motor piston, even though the valve has lap it must move until the servo-motor has been forced to bring the frequency of the controlled unit to correspond with the standard frequency. The valve cannot rest until that result has been accomplished and therefore there is no dead band.

The action is dynamic rather than static as in the case of the present governors. The smallest measurable difference in frequency between the frequency standard and the controlled turbine generator must bring about speed adjustments of the turbine. The time required to do this depends upon the gear ratio of the differential frequency measuring device which takes the place of the dashpot in this governor. The action may be slow in the case of turbines which have long water columns or fast in the case of those that are situated in open water. The correction for a speed error is along an exponential curve similar to the discharge time curve of a condenser. This correction curve need not involve over-travel which is a common characteristic of standard governors. Frequency diagrams with varying load changes may be presented in a later communication after installation of this governor in a new power plant.

It is true that the speed droop in the arrangement shown in the drawing will be affected by changes in the d-c voltage which is the source of bias for the frequency standard. However, the effect of small variations in voltage of the d-c supply is very slight. For a bias of plus or minus 2 per cent a voltage variation of as much as 10 per cent would only affect the gate position of the turbine 1/5 of one per cent and such a variation in voltage would have no effect at all if the unit were running at standard frequency for system control.

In answer to the discussion by Pickslay, I would suggest that any ordinary conventional governor would need to be in exceptionally good condition to respond to a frequency deviation as small as 1/100 of a cycle from the value at which it was adjusted, and there would be a rather small chance that this adjusted value would be exactly 60 cycles. Looseness in any of the connecting parts or valve lap might ordinarily be expected to introduce a still greater error. This means that on any system no two governors would be trying to do the same thing at the same time.

It is true that in the Warren governor integrated frequency differences between a standard value and that of a controlled unit are responsible for initiating action, and this integration of the frequency error, which can take place very rapidly, accounts for the elimination of the dead band. In this form of governor an error as small as 1/10 of a cycle of the controlled unit can produce pilot valve displacement at the rate of 0.002 inch in 1 second but the rate may be increased if desirable. This amount of frequency deviation would require 0.1 second to overcome such a positioning error of the selsyn as 2 degrees which Pickslay suggests.

Of course it is true that a frequency deviation due to a load change at one point on the system does not instantaneously appear with its full value at a remote point but the time required to return to a uniform value of frequency over the whole system is relatively brief. This would be of the order of a very few cycles, or less than 1/10 of a second. For very small variations in frequency, time lags of this magnitude in correcting gate positions of turbines are probably of far less importance than the precision with which such corrections are made.

In reply to Avery, I would say that the refinement of a needle valve was omitted in Figure 1 of the paper because it was felt that it would be generally understood that a by-pass whether through a valve or elsewhere, is an inherent part of any dashpot; the equivalent refinement of a change in the connection ratio of the comparison device to the valve was also left out of Figure 2. As regards the matter of gradual decrease of the effect of the gate motion, such a decrease is automatically obtained in the mechanism connecting the gates with the valve in the Warren governor. The governor has indeed been operated against speed droops ranging up to 25 or 30 per cent. It is true that time lags between frequency changes and governor response must be minimized; it is also true that the base for corrective response must be accurate. Figure 4 is illustrative of relatively extended interval system conditions, and is not in any sense indicative of the rapidity of action of the Warren governor. In fact, as stated in the paper, the frequency curve shown in Figure 4 was graphically derived from the recorded integrated error curve, and any time lags shown there could only be the result of a lack of precision in the graphical differentiation. There is no theoretical lower limit to the minimum lag; the governor can be designed to have as small a lag as the application requires and conditions of gate activity permit. This governor aims to provide a supremely accurate base for response, with the response as speedy as conditions external to the governor itself permit.

A 150-Kc Carrier System for Radio Relay Applications

J. E. BOUGHTWOOD
ASSOCIATE AIEE

Synopsis: The carrier system described was developed by the Western Union Telegraph Company for use with microwave radio relay circuits. Thirty-two voice-band communication channels, each 3,000 cycles wide, are derived in the frequency range 4 to 147 kc. Tandem stages of group modulators maintain a high degree of spectrum efficiency and eliminate the necessity for crystal filters. A crystal-controlled harmonic carrier supply insures the frequency stability required by narrow-band frequency-modulation telegraph circuits.

THE telegraph company has made extensive use of carrier current systems to increase the message capacity of its wire plant and currently has more than 500,000 telegraph channel miles in operation.[1] These systems have greatly improved the efficiency of traffic handling and have an excellent record for circuit continuity. Nevertheless they are still subject, at times, to interruptions from extraneous electrical disturbances and from physical damage to wire lines.

Rapid wartime advances in microwave radio techniques created new tools for the communications engineer whereby a transmission medium of tremendous intelligence-carrying capacity, and yet economically attractive, could be realized. In co-operation with the Radio Corporation of America, an experimental radio relay system operating in the neighborhood of 4,000 megacycles was developed and placed in operation between New York and Philadelphia with repeaters at Woodbridge, New Brunswick, and Bordentown, N. J.[2,3] This circuit, under constant observation since early in 1946, has demonstrated that improved continuity of operation as compared with conventional open wire lines is attainable, subject only to equipment failures at terminals or repeaters. As such failures are amenable to design and maintenance procedures, it appears that nearly the ultimate in reliability can be achieved by the use of microwave radio systems.

The radio relay systems currently being installed to link New York, N. Y., Washington, D. C., and Pittsburgh, Pa., have useful transmission bands extending from 60 cycles to 150 kc. To integrate such systems into a telegraph carrier plant standardized on a basis of telegraph channel groups designed to occupy fully voice bands approximately 3,000 cycles wide, it was necessary to subdivide the 150-kc frequency bands accordingly. Both time division and frequency division methods for accomplishing this result were considered. The somewhat uncertain status of pulse systems as to flexibility and efficiency, where maximum utilization of a restricted frequency spectrum is a major consideration, dictated the use of a single-sideband frequency-division system as the most practical method for deriving the required voice bands.

General Description

The new carrier system, designated as type *WN*, furnishes 32 independent voice circuits and occupies the frequency range between 3.9 and 147.3 kc. Each voice band provides a useful transmission path extending from 300 to 3,300 cycles, sufficient to accommodate 18 narrow-band (150-cycle spacing) telegraph carrier channels[4] or 10 wide-band (300-cycle spacing) channels. Table I illustrates the message handling capacity of the system for various modes of operation. Where the 4-channel multiplex method is employed, an excellent frequency spectrum efficiency is realized requiring but 1.7 cycles of spectrum per word minute. Although this tremendous word capacity is quite practical of attainment, it is expected that the teleprinter method will predominate, the reduction in maximum capacity being more than compensated for by other operational advantages thereby achieved.

In its fundamental concepts, the *WN* system is similar to earlier wire systems developed by The Western Union Telegraph Company. By means of tandem group modulators and filters, the load capacity of the system is increased in geometric progression with each succeeding stage of modulation. The advantages of this method are that a minimum number of translation frequencies are involved and grouping filters can utilize coils of nominal efficiencies rather than the crystal units which would be required if each voice band were raised to its assigned "line" frequency by independent modulator stages. Crosstalk and distortion due to nonlinearities in amplifiers have been reduced to negligible proportions by the use of negative feedback and conservative load ratings. Modulators are of an improved balanced bridge type capable of operating at high signal-to-carrier

Table I

Type of Operation	Type of Channel	No. of Telegraph Circuits	Theoretical Capacity in Words Per Min
Teleprinter	Narrow band	576	34,600
2-channel multiplex	Narrow band	1,152	76,000
4-channel multiplex	Wide band	1,280	84,500

Paper 48-91, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26-30, 1947. Manuscript submitted November 7, 1947; made available for printing December 10, 1947.

J. E. Boughtwood is assistant to transmission research engineer, engineering department, Western Union Telegraph Company, New York, N. Y.

The author gratefully acknowledges the advice and counsel accorded him in the preparation of this paper by the several engineers concerned in the development of the *WN* system.

Figure 1. System theory and frequency allocations

ratios without appreciable distortion. The required carrier frequencies are derived from a single base frequency oscillator and harmonic generator. A temperature-controlled crystal oscillator and associated electronic regulator circuit stabilizes the base oscillator to the desired accuracy.

A simplified system theory diagram is shown in Figure 1 with the corresponding "line" frequency allocation of each voice-band indicated. The pattern of geometric progression is quite evident in the band-frequency chart, and is employed in all but the initial modulation stage. The minimum line frequency of 3.9 kc simplifies to some extent the design requirements of various components and also eases the transmission problems encountered where the radio and carrier system equipment are remote from one another.

Table II has been prepared to illustrate the path followed by a given voice band in reaching its assigned line frequency. It shows the frequency translations encountered by a 1,000-cycle tone applied to voice band *8-C* before reaching its ultimate position at 99.8 kc. Five translations are involved and, conversely, a similar number must be traversed at the receiving terminal before the 1,000-cycle tone again appears at the output of voice band *8-C*. Voice band *8-D* also is subject to five translations, but in this case the upper side band of the 7.2 stage is selected and the resulting line frequency is 101.8 kc. Bands *1-A* and *1-B* are translated but once at each terminal. The remaining bands, of course, fall between these two extremes.

In a communication network comprising a large number of radio relay systems, certain groups of voice bands may encounter several such systems in tandem between point of origin and destination. Traffic dispatching can be expedited and equipment economy realized if these bands are grouped into blocks and each block handled as a single unit. This arrangement has been incorporated in the system by providing the patching jacks indicated by *X* on Figure 1. A 4 voice-band grouping point was selected as the most practical, although the 2-, 8-, or 16-band points could as readily be made available if desired. Greatly increased system flexibility is achieved as the equipment to the left of the indicated patch points can be moved from one system to another as traffic or emergency conditions dictate. The arrangement also permits voice band blocks to be cut through intermediate terminals without demodulating each band to voice frequency. As a result, considerable economy in equipment is realized since that portion of the system capacity reserved for spare or cut-through service need not be equipped beyond the block patching point.

The system thus divides itself into two types of modulating equipment; one designated as a voice band modulator group to combine four separate voice bands into a single block, and the other, a block modulator group, to combine eight such blocks for transmission over the radio relay circuit.

The general physical appearance of a typical installation involving two *WN* system terminals with a common carrier supply group is shown in Figure 2.

System Details

Voice Band Modulator Group

A voice band modulator group, employed to handle the four individual voice bands which make up a block, is shown schematically in Figure 3. The number of voice band modulator groups associated with a given *WN* system depends upon traffic requirements. Not more than four groups, occupying two repeater racks and furnishing a total of 16 voice bands, would be normally assigned, leaving half the system capacity

Figure 2. Typical intermediate station involving two radio relay terminals

Figure 3 (left). Voice band modulator group

Figure 4. Block modulator group

available for spare or cut-through service.

The function of the sending portion of the modulator group is to accept four identical voice bands and arrange them one above the other in the frequency range 3.9–17.7 kc. Each voice band is initially modulated by a 7.2-kc carrier, the lower side bands of *A* and *C* and the upper side bands of *B* and *D* are selected separately by appropriate filters. Since *A* and *C* now both lie in the frequency range 3.9–6.9 kc, and similarly *B* and *D* occupy the 7.5–10.5 kc-region, bands *C* and *D* are combined, and again modulated by a 21.6-kc carrier and the lower side band 11.1–17.7 kc selected. Each voice band now occupies a different part of the spectrum so that all may exist simultaneously at the output.

The receiving portion of the modulator group functions in the converse manner to restore the voice bands to their original frequency location.

Block Modulator Group

The 150-kc transmission band furnished by the radio relay circuit is channelized into eight 3.9 to 17.7-kc blocks by the block modulator group shown schematically in Figure 4. Each block will accommodate one voice band modulator group giving a maximum system capacity of 32 voice bands.

In the "stacking" of the individual blocks, the lower side band of the modulation process is utilized in all cases. At the sending terminal block 1 encounters no modulator and reaches the line in its original frequency location. Block 2 is raised to the frequency range 21.9 to 35.7 kc by a 39.6-kc modulator and paralleled with block 1. Blocks 3 and 4 are combined similarly and then translated to the frequency range 39.9–71.7 kc by an additional 75.6-kc modulator before joining blocks 1 and 2. Blocks 5 to 8 are treated identically and raised to the frequency range 79.5 to 147.3 kc by a final 151.2-kc modulator before reaching the line. Each block now occupies a different portion of the 3.9 to 147.3-kc spectrum for transmission.

The receiving portion of the block modulator group utilizes a similar method in the reverse order to restore each block to its original frequency location.

Modulator Circuits

Much has been published in connection with modulators,[8] particularly the double-balanced ring type commonly used in single-side-band carrier-suppressed systems, shown in (*a*), Figure 5. In idealized theory, this modulator is treated as a double-pole double-throw reversing switch which operates back and forth at the carrier frequency and whose reversing time is zero. Under this condition, distortion products involving harmonics of the signal are nonexistent. In practice small rectifier elements perform the switching function under control of the applied carrier voltage. For the polarities shown, elements *A-A* are polarized in the conducting direction and offer a low impedance to the signal currents, while elements *B-B* are polarized in the nonconducting direction and offer a high impedance to the signal. The output current flows as indicated. When the carrier voltage reverses, the im-

Table II

Input Frequency, Kc	Translation Frequency, Kc	Output Frequency, Kc
1.0	7.2	6.2
6.2	21.6	15.4
15.4	39.6	24.2
24.2	75.6	51.4
51.4	151.2	99.8

Figure 5. Modulator circuits

pedance conditions of the rectifiers reverse as does the output signal current. If the rectifier impedances are independent of the signal currents flowing through them, then the equivalent of true switching action can be achieved. However, with a sine wave carrier, there is a definite proportion of time at the crossover when the signaling current is equal to or greater than the carrier and during this interval severe distortion can occur. For this reason, the ratio between carrier and signal powers must be large if distortion in wide-band group modulators carrying a multitude of separate signal frequencies is to be maintained at an acceptable level. A logical solution is to employ a square wave carrier voltage which switches the rectifier elements abruptly between the conducting and the non-conducting conditions and reduces to negligible proportions the time interval during which the signal can influence the rectifier impedances. A reduction in distortion components of at least 25 decibels can be achieved easily by this method. Another factor which may seriously limit the load carrying capacity of the double-balanced modulator can be explained by reference to the equivalent circuit shown at (*b*). Idealized rectifiers are assumed having a low resistance R_f when polarized in the conducting direction and a higher resistance R_b when polarized in the nonconducting sense.

The signal voltage across a conducting rectifier is

$$E_s = V_s \frac{R_f}{2(R_L + R_f)}$$

The carrier voltage across a conducting rectifier is

$$E_C = \frac{I_C}{2} R_f$$

where I_C is the total carrier current.

For a square wave carrier and idealized elements, overload will be reached when $E_s = E_C$ or

$$V_s(\max) = I_C(R_L + R_f) \qquad (1)$$

Similarly for a nonconducting element

$$E_s = \frac{V_s}{2} \text{ approximately}$$

$$E_C = \frac{I_C}{2} R_f \text{ as before}$$

Overload again occurs when $E_s = E_C$ or

$$V_s(\max) = I_C R_f \qquad (2)$$

Obviously equation 2 is smaller than equation 1 and is the first to be exceeded as the signal input is increased. In a typical case where $R_L = 600$ ohms and R_f about 50 ohms, the nonconducting rectifiers will overload with a signal less than one-tenth that required to overload the conducting branches.

This condition is remedied easily by increasing the carrier voltage across the nonconducting elements. Diagram (*c*) shows one of several possible methods for accomplishing this result, in this case by adding resistors R in series with each rectifier element. Although this method, in contrast to other possible methods, introduces some loss in the signal path, it is preferred because of its simplicity and excellent balancing properties.*

Germanium rectifier elements with either welded or pressure contacts replace the copper-oxide type used with previous carrier systems. They are more stable with respect to temperature and mechanical shock so that modulators employing these elements have excellent balance stability. This is an important consideration in sending modulators where the desired sideband and the carrier frequency are in such close proximity as to prohibit adequate carrier suppression by the grouping filters alone. By adding the balancing potentiometers P_1 and P_2 as indicated in diagram (*d*), the fundamental carrier output can be suppressed to any desired degree. In the receiving demodulators the desired side band and the carrier are always widely separated so that a precise carrier balance is not necessary.

A power level of plus 10 decibels referred to one milliwatt at the voice-band patching point is the standard level employed by the telegraph company for all carrier systems. To maintain this level throughout the modulator stages of a *WN* system would require electronic components of large power carrying capacity. Therefore, the 7.2-kc sending modulators are designed for a single side-band loss of 30 decibels so that voice-band loads entering the system at plus 10 are reduced to minus 20, this level being maintained throughout the sending terminal by single-tube low-power amplifiers associated with each modulator stage and having sufficient gain to compensate for filter losses.

The receiving terminal operates at a somewhat higher level to insure an adequate margin of adjustment when block patching between different systems. For this reason and also because distortion components in the demodulator amplifiers, particularly those involving harmonics and difference products of the signal frequencies are so located as to produce crosstalk between bands, 2-tube amplifiers of higher power capacity and lower distortion than the corresponding units in the sending terminal are employed. The final 7.2-kc receiving demodulator has sufficient gain and power output to restore the individual voice bands to the standard plus 10 decibels referred to one milliwatt level.

To facilitate system adjustment and

Figure 6. Voice-band transmission frequency characteristic

maintenance procedures a high-frequency 600-ohm decibel meter was developed. The meter is a rectifier type similar in principle to the current instrument used with lower frequency wire line carrier systems.[6] Germanium crystal rectifier units and a shielded high-frequency adjustable attenuator network are employed to obtain a flat frequency response. The response at 1,000 kc is down only 0.3 decibel. Levels between minus 15 and plus 35 decibels referred to one milliwatt can be measured with an accuracy of 0.2 decibel in the 150-kc range.

Filters

The excellence of a carrier system depends to a large extent upon the quality of its filters. The design of the *WN* system filters, covered in a current paper,[7] are predicated on a minimum signal-to-crosstalk ratio of 50 decibels for each voice band, a quite adequate margin for carrier telegraph service and sufficiently great to allow many such systems to operate in tandem. The end impedances are 600 ohms and sufficiently well balanced with respect to ground to mitigate the effects of longitudinal voltages which may be induced in external wiring. Both block and voice-band patching points are equalized where necessary to maintain a substantially flat frequency characteristic. The transmission-frequency characteristic of a typical voice band, showing the effect of the equalizing network, is given in Figure 6.

Terminal Repeater

The function of the terminal repeater, Figure 7, is to bridge the gap between the channelizing equipment and radio relay terminal and to provide necessary monitoring and talking facilities. A pilot channel operating at 19.8 kc gives a continuous check of the circuit transmission equivalent and also may serve as a Morse or teleprinter talk circuit. A service phone channel occupies the unused portion of the spectrum below 3 kc. The line coupling panels match the 600-ohm terminal impedance to that of the particular circuit connecting to the radio terminal. Where the circuit is of appreciable length, receiving equalizers maintain a flat frequency characteristic.

Carrier Supply Group

A measure of the frequency stability of a carrier system is the maximum amount by which voice frequencies, after passing through the system, differ from the frequencies originally transmitted. Frequency modulated telegraph channels will be subject to bias losses if this difference is excessive. The possibility of such losses is reduced to negligible proportions in the *WN* system by designing the carrier supply group for a frequency stability of better than 0.00066 per cent.

It may be of interest to illustrate the relation between a given frequency error in the system base oscillator and the resultant error in the line frequency assignments of the various voice bands. In a carrier system employing tandem stages of modulation where the lower side band in each stage is utilized, the line frequency error is

$$\Delta L = \Delta C(n_1 - n_2 + n_3 - n_4 \ldots \text{etc.})$$

where ΔC is the base frequency error in cycles and n_1, n_2, etc., are the harmonic relation of the carrier frequencies to the system base frequency, listed in the order used. For example the line frequency error in voice band *8-C* (see Table II) for $\Delta C = 0.1$ cycle would be

$$\Delta L = 0.1(2-6+11-21+42) = 2.8 \text{ cycles}$$

For a given base frequency error lower-side band method of tandem operation introduces no greater line frequency error than systems employing individual modulators for directly translating each voice band to its line frequency assignment.

A schematic layout of the carrier supply group is shown in Figure 8. Regular and spare supplies are identical and are energized by separate power distribution circuits for added reliability. A 3.6-kc temperature-controlled *LC* oscillator of good stability is employed to generate the system base frequency from which the carrier frequencies are derived in a conventional manner by means of a harmonic generator and appropriate harmonic selection filters.

A temperature-controlled crystal oscillator operating at 151.2 kc is employed to monitor continuously the highest translating frequency, also 151.2 kc, derived from the harmonic generator. Monitoring is accomplished by a frequency control unit, essentially a phase detector, whose output voltage is proportional in magnitude and polarity to the phase difference between the two sources. By applying this voltage to a reactance tube frequency control circuit incorporated in the base frequency oscillator, exact synchronism between the two sources is maintained. Thus the frequency stability of the entire terminal is identical to that of the crystal oscillator and well within the desired limits. Al-

though this control arrangement may be somewhat unusual because of the high degree of frequency multiplication involved (42d harmonic of 3.6 kc), properly designed damping characteristics render it completely stable in operation.

A meter in the frequency control unit indicates the amount and polarity of the correction voltage being applied to the base oscillator. An associated alarm relay gives an audible and visual indication in the event the correction voltage should exceed 50 per cent of its maximum allowable value, enabling the attendant to manually retune the base oscillator without interrupting the circuit. The crystal oscillator may be varied over a limited frequency range sufficient to compensate for differences in various crystal units and to permit frequency matching of all carrier supplies to a given standard.

A high degree of reliability is secured by providing duplicate sets of carrier generating equipment. Associated switching arrangements transfer the load from one to the other either automatically or under manual control. The carrier switching panels contain two cathode-follower amplifiers each actuated by corresponding frequencies from the regular and spare carrier supply groups. A single output transformer is switched mechanically into the cathode of the appropriate amplifier, furnishing a very low impedance carrier source to energize the carrier bus. The busses normally are energized by the regular supply and their power levels are monitored individually by meter relays. A failure on any bus causes the corresponding meter relay to operate and transfer the entire office load to the spare supply where it will remain until manually restored. The level of each carrier frequency from the idle supply also is monitored at all times to insure its readiness in case of need.

The carrier switching control panel provides visual means for indicating which supply group is carrying the office load and in the event of a failure, indicates on which group it occurred. A master switch disables the automatic feature and permits manual control to be established for testing and maintenance purposes. In addition to a visual indication, an audible alarm is sounded upon the failure of any carrier frequency, regular or spare.

A frequency distribution network inserts protective resistors between each carrier frequency bus and the multipled feeders for supplying the various *WN* systems in an office so that faults on any particular feeder group will not affect the levels on the other groups. Up to eight system terminals can operate from a single carrier supply group. The carrier frequencies are converted into the desired square wave form by appropriate amplifiers associated with the voice and block modulator groups. Each amplifier has sufficient power output to operate eight modulators.

Automatic and manual switching is also provided in connection with the regular and spare 151.2-kc crystal-controlled oscillators. Provisions are made for indicating the frequency difference between the two oscillators and for comparing them independently with a standard frequency source.

Performance

Signal-to-noise measurements on individual voice bands with all remaining bands carrying multichannel telegraph traffic averaged better than 50 decibels. This margin is quite adequate for tandem operation of as many systems as reasonably might be required to cover the continental United States and yet maintain a signal-to-noise ratio sufficiently great for telegraph and facsimile service. With the system operating over a radio relay circuit consisting of two terminals and seven repeaters, the comparable signal-to-noise ratio was approximately 43 decibels.

Observations of frequency stability over a period of several weeks indicated the maximum frequency shift in any voice band to be not greater than one-fourth cycle per second.

ASSOCIATE AIEE

Synopsis: This paper describes the filters developed for use in subdividing a frequency band of approximately 150 kc into 32 voice bands, each 3,000 cycles wide. A system of modulation in which each successive stage carries twice the number of voice bands found in the preceding stage reduces to six the total number of different frequency bands requiring separation by means of filters. Economy in cost and mounting space is attained through use of filter types which minimize the number of inductive elements required. Highly stable powdered iron cores are used in all inductive elements.

IN the wire line carrier systems now widely used in the telegraph company's plant, a voice frequency channel having a band width of approximately 3,000 cycles constitutes the basic unit. This basic unit may be broken down into a number of narrower channels for teleprinter or multiplex operation or may be used as a whole for facsimile or telephone transmission. Additional bands required to utilize the available signal carrying capacities of the various systems are obtained by means of modulators. The translating carrier is suppressed and only one of the side bands resulting from the modulation process is retained. The other first-order side band and any interfering higher order side bands are rejected by suitable filters.

In carrier systems where the total number of voice frequency bands that must be so derived is small, the design of filters required to select the single desired side band and reject all the other unwanted frequencies has not presented difficult problems. However, in a system capable of handling 32 bands of signaling frequencies each 3,000 cycles wide and extending up to 150 kc, much more difficult filter design problems are presented. One solution is the crystal filter. Another is described here and in a current paper.[1]

In order to simplify the filter design and at the same time to utilize efficiently the 150-kc wide band and retain the 3,000-cycle voice frequency band as the basic unit, a scheme of multiple, or consecutive, modulations was adopted.[2] The resulting system has been designated as type *WN*. In this arrangement only two of the side-band selecting filters have 3,000 cycle band width, and moreover they occur at the lowest frequency positions in the system. At subsequent modulation points the filters select groups of 2, 4, 8, or 16 bands. A geometric progression in filter band widths is the result, with an approximately constant ratio between band width and location of the band in the 150-kc spectrum. Details of this system are shown in Figure 1. As the figure shows, only six different frequency bands in various parallel arrangements are required to yield a total of 32 voice bands.

All the filters have relatively wide pass bands in terms of the ratio of upper cutoff to lower cutoff. This ratio is roughly two in all six bands. For instance, the lowest frequency filter of the series has a lower cutoff of 3,600 cycles and an upper cutoff of 7,100 cycles and the highest frequency filter has a lower cutoff of 76,200 cycles and an upper cutoff of 152,000 cycles.

Figure 1 shows the useful signal frequencies as distinguished from the cutoff frequencies, and it may be observed that it is never necessary to filter out frequencies less than 5.5 per cent away from the signal. Since the various 3,000-cycle bands must be suitable for facsimile or speech transmission, a signal to noise ratio of 50 decibels or more is desirable and that value is realized throughout the system. It may be accomplished by a

The author is very grateful to A. Boggs for inspiration and constructive criticism, to Mrs. C. U. Watts who did much of the design work, and to T. Rystedt and P. P. McLaughlin who did most of the testing.

Figure 2. Successive stages in design of typical filter

combination of two filters or a combination of modulator balance and filter attenuation but the end result is interference 50 decibels below the signal.

In the design of the filters, the number of inductive elements was kept at a minimum since coils usually require more space and are more expensive than capacitors. This principle was applied most intensively to the lower frequency bands since they account for the major share of cost and space in the system. It proved to be possible to develop the required discrimination with five coils and a somewhat greater number of capacitors in each of the three lower frequency bands. The higher frequency filters were permitted more coils since used in much smaller quantity.

Typical Filter

As an example of these filters, consider the filter shown schematically in various stages of development in Figure 2 and indicated by the numbers 3.9–6.9 in Figure 1. It follows a balanced modulator fed with a 7,200-cycle square-wave carrier frequency and a 300 to 3300-cycle signal band. It must deliver the first-order lower side band of that modulation (3,900 to 6,900 cycles), with the upper side band, signal leak, and higher order modulation products suppressed far enough to result in a 50-decibel signal to noise ratio. Since the balance of the modulator may be depended on for 30-decibel suppression of the signal leak, the filter needs to supply only 20-decibel attenuation at frequencies less than the useful signal band; however, it must supply the full 50 decibels unaided at the upper side-band frequencies. Since the carrier is a square wave, the third order products ($3c \pm s$) are only about 10 decibels below the useful signal level and the filter must supply 40 decibels attenuation. It is evident that if efficient use of filter elements is to be had, a quite dissymmetrical filter characteristic is required and most of the m-derivation peaks need to be on the high frequency side. The resulting measured attenuation curve is shown together with the straight line curve of requirements in Figure 3.

The various stages of development from the design schematic to the final balanced network are shown in Figure 2. There are a number of steps in the selection of the component filter sections, and in the transformation from the design schematic to the final form which may be of interest, since many filter design sources do not list them. In order to provide a basis for discussion the filter sections considered, together with their m-derivations and design formulas, are given in Figure 10 of Appendix I. In the notation of Figure 10 the filter shown in Figure 2 is made up of five half-sections of type *3B2*, two half-sections of type *3C1*, and one half-section of type *3B* with m-values as shown in the first schematic of Figure 2.

Both the *3B2* and *3C1* half-sections consist of three capacitors and one coil and provide one peak of attenuation which meets the requirement of minimum inductive elements and permits independent assignment of peak attenuation frequencies. One peak of attenuation can be realized for every coil in a band pass filter and they may be assigned at will on either side of the pass band. (In this filter one of the peaks is at infinite frequency.) The selection of m-values and section types was done by trial and error to fit the required attenuation characteristic with the minimum number of coils, all the section types of Figure 10 being considered.

The section junctions on each side of the *3C1* section may at first sight appear to be mismatched, but according to Figure 10 the mid-shunt surge impedance of type *3B2* and the mid-series surge impedance of type *3C1* differ only by the constant factor $(1+f_1/f_2)^2$, and therefore can be perfectly matched by a suitable choice of impedance level in the *3C1* section, or by use of the "ideal transformer" technique as outlined in Appendix II.

In the *WN* system filter selected for detailed description, several capacitances are larger than is desired for economic application of mica capacitors at a 600-ohm impedance level. To reduce these capacitances, an ideal transformer was applied at four places (shown by the brackets in the second schematic of Figure 2), using the formulas of Appendix II. The result is shown in the third schematic of Figure 2 and was sufficient to reduce the capacitances to satisfactory values while leaving the terminal characteristic impedances unchanged.

The final form is shown in the fourth and last schematic of Figure 2, and is obtained from the third by converting a T of capacitors into a Π and balancing the circuit against longitudinal disturbances.

Figure 6. Measured attenuation of 151.2-kc filter

The three parallel resonant circuits in the series branches of the design schematic are not treated alike in the final schematic. The method using three windings on a common core as in the $m=0.75$ section is preferable from balance and manufacturing standpoints but introduces four times the leakage reactance in the series branch. This unwanted leakage inductance tends to reduce the attenuation when series resonant, which effect can be shifted to about twice the frequency by the method used on the $m=0.4$ and $m=0.55$ sections. The effect can be eliminated entirely by applying the tuning capacitor to both halves of the series coil but that did not prove to be necessary in this case. An alternative procedure would be to increase the amount of interleaving of the windings but that is always inconvenient for the manufacturer.

The input and output impedances of a filter are always important in determining the flatness of the attenuation-frequency characteristic in the pass band, and in five of the six frequency bands an m-derived characteristic impedance ($m=0.5$) is obtained at the line end by the fractional end branch termination required for satisfactory paralleling and described in subsequent paragraphs. The sixth filter obtains a similar result illustrated in curve *G* of Figure 4.

For the higher frequency bands a conventional 6-element symmetrical m-derived section ($m=0.55$ or 0.65) is used at the set end, but for the lower frequency bands the limitation on coils caused the use of less uniform impedances such as those described by the equation for Z_{01} of *3B2* in Figure 10. In the case of the filter of Figure 2, the set-end impedance is Z_{01} of *3B2* with $m=0.75$, which is similar to the familiar constant K impedance with which it is identical if $m=1$.

Modifications for Paralleling

Having secured a satisfactory attenuation characteristic for the individual filters it remains to make sure that the performance is not degraded when they are paralleled in service. Fortunately it is possible to make the paralleling filters improve the performance of the one being measured, as has been well described in the literature,[3] so that only a brief sketch of the method is appropriate here. The basic principle states that a constant (or nearly constant) resistance in series with a reactance of similar or smaller magnitude results in a suceptance-frequency characteristic of negative slope which can be used to resonate or cancel a conventional susceptance, not at a single frequency, but over a band of frequencies. That is, each of a group of parallel connected filters can be made to have a negative slope susceptance in its pass band where its surge impedance is resistive, but will retain a positive slope sus-

ceptance outside the pass band. The combination of these positive and negative slope susceptances produces a kind of antiresonance in the pass band of each filter, leaving the real part of the input impedance unshunted by the paralleling filters. Mathematically this inverted susceptance arises from the negative sign on the right-hand half of the following equation whenever R is large enough to hold the magnitude of the denominator substantially constant.

$$\frac{1}{R+jX}=\frac{R}{(R^2+X^2)}-j\frac{X}{(R^2+X^2)} \qquad (1)$$

A graphical representation of the admittance of a single filter is shown in Figure 4 for three cases; the added reactance series resonant at the lower cutoff, mid-band, and upper cutoff frequencies, respectively.

The sum of the six susceptances in the signal bands of these filters has been calculated to be less than 50 per cent of the line conductance, and similarly a departure of 25 per cent is calculated for the conductance. It is recognized that smaller tolerances than these can be obtained by more complex susceptance annulling networks but it is believed that a good economic compromise has been reached. The added series resonant series branch is included in the schematics of Figure 2, although not mentioned in the discussion of that figure, for the sake of clarity.

Measured Attenuation

The most important parts of the measured attenuation curves of the six filters are shown in Figure 5. The combined effects of dissipation and imperfect termination are about one decibel at the edge of the signal spectrum in all the filters, and any departure from a smooth curve in the central part of the pass band is less than one-tenth decibel. The result is 32 voice bands in a frequency spectrum of 143.4-kc band width or 4,480 cycles per 3,000-cycle band, a spectrum efficiency of 67 per cent. Two filters assembled on a doubledeck rack panel are shown in Figure 7.

There are a few narrow band filters in the *WN* system used to select pilot tones and oscillator harmonics that are of slightly unusual construction. They are made of *3C* sections, mid-shunt terminated, and therefore must be connected to a common source or load in series rather than in parallel. This arrangement is used to avoid the high inductance series branch coils with their troublesome low Q and humidity coefficients, and at the same time have a convenient inductive impedance transformation to obtain the most reasonable capacitances in the rest of the filter. Figure 6 shows the measured attenuation of such a filter centered on 151.2 kc and with a nominal band width of 1,200 cycles.

Coils and Capacitors

Of the available coils, the ones most suited to this work use a shell type dust core with a heavy copper shield illustrated by Figure 8. They provide a Q as shown in the shaded area of Figure 9, the variation at any one frequency depending on nearness to self-resonant frequency, wire diameter, and copper space factor. They have adequate stability when subjected to varying temperature and signal levels. The temperature coefficient of inductance is approximately plus 50 parts per million per degree centigrade, and the total change of inductance with flux density reaches one part per thousand only at levels well above the operating point. The change of Q with level is much greater, but of less importance since it is effective only at the "corners" of the propagation characteristic and any changes at normal signal levels are too small to measure.

The coils are easily manufactured with an inductance tolerance of plus or minus two per cent. Only a small percentage of rejects is found and those outside inductance limits are easily adjusted to the required value by air gap spacers.

The capacitors used are the usual commercial mica capacitors in sizes from 0.00015 to 0.07 microfarad with an average of 0.02. They are given an aging treatment by means of temperature cycles and selected in groups of three or less to values accurate to plus or minus one per cent. This requirement is placed on capacitors not associated with a peak of attenuation, and a corresponding requirement of one-half per cent of specified frequency is placed on the frequency of attenuation peaks. (The oscillator used for adjustment is required to be accurate to one-tenth per cent in order not to contribute important errors to the measurements.)

Appendix I. Three-Element Filter Sections and Their *m*-Derivations

The four well-known 3-element filter sections[3,4] are shown in Figure 10, each grouped with its two *m*-derivations and with formulas for element values, dissipationless apparent propagation constant, and surge or image impedance. This grouping of the sections is chosen to emphasize the *m*-derived relation between sections such as *3B* and *3B1*, frequently obscure in the literature, and to place on an equal basis the alternative *m*-derivation, such as *3B2* usually missing from tables of filter design formulas. This omission probably results from the rapidly varying surge impedance–frequency characteristic which, with a few exceptions, limits their use to the body of the composite filter.

All formulas for element values are given for half sections rather than full sections since it has been the author's experience that half sections are the building blocks used by the designer. The half section element equations always contain 2π in the denominator while the full section formulas have either π or 4π. (The 2π would disappear if angular velocity were used instead of frequency.) The apparent propagation constant, $\sqrt{ZY}$, for the half section is identical with the full section parameter $\sqrt{Z_1/4Z_3}$ of Guillemin[3] and Shea.[4] The square root is shown since the real propagation constant, θ, is approximately equal to $\sqrt{ZY}$ to the degree that θ approximates $\sinh\theta$.

The 3-element branches have been transformed to that canonical form exhibiting the peak forming elements as simple series resonant or parallel resonant elements, for convenience in testing or trouble shooting. Some of the formulas are more complicated when so transformed, but not prohibitively so. Convenient tables[5] are available to aid in evaluating the equations.

The element and surge impedance formulas are given for a 1-ohm filter since some economy of design effort may be realized in that way. It is understood that all in-

Figure 12. Example of ideal transformer use

ductances are to be multiplied and all capacitances are to be divided by the nominal circuit impedance at the end of the design work. The symbols are largely self-explanatory but for completeness the following list is given.

f_1—Lower cutoff frequency.
f_2—Upper cutoff frequency.
f_a—Frequency of peak attenuation.
Z_m—Mid-series surge impedance.
Z_{sr}—Mid-shunt surge impedance.
m and B—Design parameters related to f_a.

It may be observed from the formulas of Figure 10 that as m varies from one to zero the m-derived surge impedance varies between limits defined by the two surge impedances of the prototype. A more nearly constant result can be obtained from such sections as *3A2* and *5B1* than from *3A1* and *3B2*.

Appendix II. Ideal Transformers

The following method for using ideal transformers has been found convenient as it avoids consideration of negative elements and provides a useful tool for changing impedance levels in an otherwise completed filter design. It is similar to the discussion of pages 135–6 of reference 4.

To avoid having to reverse mentally the direction of a schematic diagram in which a transformation is desired, we can introduce four ideal transformers as in Figure 11 and then in any application retain only the one needed and cause the other three to vanish by making their turn ratios unity. If the two schematics of Figure 11 are to be equivalent then their impedance matrices[3] must be equal, term for term.

$$\begin{Vmatrix} \dfrac{Z_1+Z_2}{A^2} & \dfrac{B}{A}Z_2 \\ \dfrac{B}{A}Z_2 & B^2Z_2 \end{Vmatrix} = \begin{Vmatrix} C^2Z_4 & \dfrac{C}{D}Z_4 \\ \dfrac{C}{D}Z_4 & \dfrac{Z_3+Z_4}{D^2} \end{Vmatrix} \tag{2}$$

which leads to the following equations

$$Z_1/Z_2 = Z_3/Z_4 = AC/BD \tag{3}$$

$$ABCD = 1 + Z_1/Z_2 = 1 + Z_3/Z_4 \tag{4}$$

As an example, suppose it is desired to introduce an ideal transformer as in Figure 12. The turn ratios A, C, and D will be unity. B will equal $1 + 1.5/0.5$ or 4, and the second schematic is equivalent to the first. It should be noted that after the transformer is introduced, the series impedance is always on the high impedance side of the circuit, or in other words the configuration of the circuit determines whether the ideal transformer will step up or step down. A, B, C, and D are either unity or greater than unity.

Oil Film Thickness Indicator for Journal Bearings

M. L. GREENOUGH
NONMEMBER AIEE

THE oil film thickness indicator was developed in connection with a general program of engine instrumentation for use in journal bearing studies. This instrument was specifically designed for the determination of the thickness of lubricating oil in a machine for testing experimental sleeve-type bearings. Actually the instrument shown in Figure 1 measures the clearance between shaft and bearing in all angular positions. However, its principle of operation is adaptable to many other problems involving measurement of small clearances or thicknesses.

In this particular problem, it is desired to measure film thickness in a six-inch diameter bearing with a radial clearance of about 0.006 inch. Since the rotational speeds might be in excess of 10,000 rpm, it is felt advisable to have no physical contact with the shaft, nor should the measuring system affect the bearing performance in any way. The system must operate in an atmosphere of, or submerged in, lubricating oil at 200 degrees Fahrenheit. Cleanliness of the oil is maintained by filters in the oil circulating system.

Many systems for the measurement of oil film thickness in journal bearings have been described in the literature, some of which are listed with the references at the end of the paper. Among these are mechanical-optical and optical interference methods, as well as capacitive and low-frequency magnetic systems. For the application described, however, a mutual inductance type of electrical distance measuring element appears to offer the most satisfactory solution. Its linear response makes it highly suitable for use in combination with a cathode ray tube in a system where the end indication is a polar diagram of shaft displacement from bearing center. These elements meet the necessary requirements as to linearity, frequency response, immersion in oil, and stability. The coupling between two air core coils at radio frequency is varied by the proximity of a metallic surface, such as the shaft. Since this metal is preferably nonmagnetic, the shaft is electroplated with a thin layer of copper in a band immediately under the distance-sensing elements. No electrical contact to the shaft is required.

Four distance-sensitive elements, or probes, mounted in positions 90 degrees apart immediately beyond the bearing area are used for the determination of radial shaft displacement. By impressing the signal from each probe on a corresponding deflection plate of a cathode ray tube, it is possible to recreate the polar diagram of shaft center displacement or eccentricity, magnified many times. Since means are provided in the instrument for determining the total clearance between shaft and bearing, subtracting the eccentricity from the value of radial clearance yields the oil film thickness. Inasmuch as the clearance may be altered by differential thermal expansion of shaft and bearing, provision to make such measurements during any part of the test is necessary.

Co-ordinate and Measurement System

Figure 2 shows a schematic picture of an off-center shaft. A, B, C, and D are the distances from the bearing to the circular shaft at the four probe positions. The electrical signal from each probe is in the form of a d-c voltage proportional to the spacing between bearing and shaft. Connection to the cathode ray tube is such that an increase in spacing causes a beam motion away from the corresponding probe position, with zero signal causing zero deflection from center. Thus, if the journal were the same size as the bearing, the spot on the cathode ray tube screen would lie on the center of the screen whether each probe alone or all four were connected. With the shaft free to move in the bearing, the components of shaft displacement are picked up by the probes and transformed into voltages. These voltages, when applied to the deflection plates of a cathode ray tube, cause similar displacement components of cathode ray tube beam. Because of the over-all strict proportionality between shaft and beam motions, and of the correspondence of probe and deflection plate angles, the spot position on the screen is an accurate reproduction of shaft eccentricity at all times.

The diametral clearance is the difference in diameters of the bearing and journal, and for practical purposes is equal to the sum of the clearance indications from any pair of opposite probes. In the instrument this sum is most conveniently obtained by determining the individual clearances separately, adding the two manually. Since the deflection for a single probe is not in push-pull, a factor of 1/2 relative to the deflection caused by a pair of probes is introduced. The sum of two opposite clearances obtained should be the same regardless of which pair of probes is used, and should be independent of shaft location in the bearing. For vibratory conditions, the average spot displacement could be taken for determining radial clearance.

Paper 48-96, recommended by the AIEE joint subcommittee on electronic instruments and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 13, 1947; made available for printing December 16, 1947.

M. L. Greenough is with the National Bureau of Standards, Washington, D. C.

This instrument was developed in the Electronic Instrumentation Laboratory of the National Bureau of Standards as part of a program for the Navy Department, Bureau of Ships. The collaboration and assistance of J. G. Reid, Jr., H. H. Parnell, W. E. Williams, Jr., J. Johansen, and A. Soler of the Bureau of Standards, is appreciated. Grateful acknowledgment is also given to W. V. Smith and M. Levinsohn of the Engineering Experiment Station at Annapolis for their participation in the development and test program.

The scale with which clearances are read is graduated for push-pull deflection for ease in reading eccentricity. When all probes are connected to deflection plates, which is the normal connection for observing eccentricity, the deflection along a probe axis is due to the combined effect of two opposite probes. Hence, the indication for each probe alone is one-half of the actual clearance at the probe position. With all four probes connected, each to its corresponding deflection plate, the system furnishes a continuous indication of eccentricity. In the absence of vibration the spot assumes a position indicative of the eccentricity. Vibration if present causes the spot to trace some closed loop which is a replica of shaft vibration in the bearing.

Figure 3 shows how oil film thickness measurements may be made at any point on the periphery of the bearing. It has just been shown how a magnified picture of eccentricity is displayed on the cathode ray tube screen. To determine the oil film thickness at any point around the bearing, it is necessary to subtract the eccentricity vectorially from the value of radial clearance. The actual film thickness at any point is the radial clearance minus the component of eccentricity along a line drawn from bearing center to the point under study. The eccentricity also has components perpendicular to the line from bearing center to the point under study. A rotating set of rectangular coordinates, with the origin at the true bearing center is therefore required. At the point on the bearing wall, eccentricity may be considered as made up of radial and tangential components. The tangential component is zero at the point of minimum film thickness. For a study of oil film thickness it is usually not necessary to identify a point on the bearing wall to much better than one degree, or about 0.05 inch on a 6-inch shaft. Since in a typical bearing the maximum eccentricity is limited to the 0.006-inch radial clearance value, the tangential component of eccentricity is therefore much less than the normal tolerance of angular determination, and may be neglected.

Figure 4 shows the scales on the cathode ray tube screen. Around the periphery is the angular scale, calibrated in degrees measured in a clockwise direction from the reference axis. The transparent rotatable scale is mounted so that its center is coincident with that of the cathode ray tube, which also corresponds to the center of the bearing. The rotatable scale carries the axes for measuring the component of eccentricity in any desired direction. A pointer on the base line of the scale, when read against the angular scale, shows the angle of the line from bearing center to the point under test. To assist in reading the component of eccentricity along this line, perpendicular graduation lines are provided. These are located at intervals equivalent to 0.001-inch displacement of the shaft. The particular scale on this instrument is marked from zero in the center to ±0.013 inch on the outside, providing a margin beyond the required ±0.006 inch. Since these lines are 0.150 inch apart, an overall amplification figure of 150 may be ascribed to the system. It by no means represents the maximum for systems operating on these principles, but was chosen as a convenient value, meeting the requirements for this instrument.

Operation with these scales is quite simple. To measure eccentricity and the angle of closest approach, the rotatable scale is turned until the base line passes through the spot on the tube screen. The eccentricity is read on the graduations on the base line, while the angle is indicated by the location of the pointer over the angular scale. To make measurements at any other point, the rotatable scale is turned until the pointer indicates the desired angle from the reference axis. Projection of the eccentricity on the base line is again read with the same graduation lines. The radial clearance is obtained by summing the indications from two opposite probes, the proper connections being made by a selector switch. Subtracting the component of eccentricity just measured gives the oil film thickness at the point under study.

In many cases it is not feasible to mount the probes on axes which are parallel and perpendicular to the line of action of load. Rotation of the cathode ray tube, but not the scales over its screen, by an amount equal to the differences in angle between probe axes and load line, restores correctness of displacement indications.

Distance Measuring Elements

A suitable system of electrical distance measurement was developed on the principle of variation of mutual inductance

Figure 4. Scales used on screen of cathode ray tube for determination of oil film thickness

between coupled air-core coils excited at radio frequency. Suppose that a primary coil is excited by radio-frequency current, and that the plane of the coil is parallel to a nearby metal surface. Figure 5 shows such an arrangement. Let it be assumed that the metal plate is of a perfectly conducting material. Under such conditions, the electromagnetic field at the surface of the plate is exactly cancelled by the field of the eddy currents induced in the plate. A secondary or probe coil placed just at the surface has no voltage induced in it. If the probe coil is moved away from the plate toward the exciting coil, it will be found that an increasing voltage is picked up as the probe coil is placed closer to the primary coil. The voltage output of the probe coil can then be used as an indication of the gap between it and the metal surface.

Such a system has mechanical disadvantages, because of the necessity for flexible leads, for instance. An improvement is to mount both the exciting and probe coils on one form, and to move this coil assembly with respect to the metal. The same basic principles still apply. Although the strength of the exciting field is no longer constant at the metallic surface, the resulting correction to the effect of variable distance from probe coil to plate is small, so that there is not much loss in scale factor. At the same time the device becomes readily adaptable for many applications.

A typical relation of mutual inductance between the two coils versus spacing from the end of the coil form to plate is shown in Figure 6. This relation is apparently linear up to about five per cent of the diameter of the coil form. Linearity to better than one per cent is not difficult to secure over this range. One commonly useful size of coil form is one inch in diameter, permitting linear measurement up to 0.05 inch. This graph also shows the difference between the relative variations of mutual and self inductance, although the plot of self inductance may not represent optimum design for a single coil. The change of self inductance is much smaller than that of the mutual coupling, and in addition, is not linear over any appreciable range.

For several reasons, the mutual inductance is not zero at zero spacing. The probe coil cannot be located at the surface of the metal because it must have finite size and enough wall thickness for mechanical rigidity. A factor of lesser magnitude is the effective skin depth of the metal itself. The resulting initial mutual coupling may be cancelled in some instances by employing a third coil on the same form mounted close to the exciting winding, so that coupling between it and the exciting coil is relatively unaffected by the proximity of the metal. It is connected in series opposition with the probe coil, and is adjusted for zero total mutual coupling between input and output circuits when the metal surface is at the end of the coil form. When, as in this instrument, the probe coils are utilized to produce a d-c signal voltage, the initial coupling may be offset by inserting in series a bucking d-c voltage.

Considerable experimental investigation has been made of the effects of different geometrical arrangements of the coils. The characteristic shown in Figure 6 can be made concave upward or downward, as well as linear. The optimum form has been found to be two concentric, coplanar coils, one having an average diameter 0.68 to 0.70 that of the other. Maximum change of mutual inductance over the greatest linear range has been secured from this design. Since solely a mutual inductance phenomenon is involved, it makes no difference which slot

Figure 5 (left). Basic structure of distance-measuring element used in oil film thickness indicator. Mutual inductance between two coils is varied by proximity of metallic surface

Figure 6. Variation of self and mutual inductance as used for electrical measurement of distance

is chosen for the primary winding. As long as the primary coil is always wound with the correct number of turns for the same value of inductance, provided the same procedure is followed for the secondary, the performance is identical.

It has also been found that one coil may be somewhat distributed, if the other is concentrated close to the end of the form, as shown in Figure 7*C*. This may be inferred from the cross-section views of Figure 7*A* and 7*B*, where a coplanar form is shown in 7*A*, and a "staggered" form is given in 7*B*. Again, either slot may be used for the primary winding. In spite of the slightly increased initial coupling, the greater coil area permits the use of larger wire or more turns, both of which may be advantageous when the larger slot is used for the primary, as is usually the case. The higher Q of a coil having larger wire necessitates less power input for a given value of volt-amperes. Also, the heat dissipating area is much greater. Secondary coil resistance is generally immaterial, so that the wire is usually chosen small enough to accommodate the desired number of turns.

The graph in Figure 6, showing the variation of mutual inductance as a function of distance, is for measurements to a flat metal surface. When the surface is curved, the relation is the same, except that the origin on the abscissa (distance) scale is shifted by amount equal to the effective average minimum distance. It is apparent that the initial coupling is greater, and that the useful linear range is reduced. The greater the curvature of the surface, the more pronounced are these effects. In this instrument, the curvature of a 6-inch shaft gives rise to an initial coupling equivalent to about 0.02 inch greater than that to a flat plate.

The graph in Figure 6 is also for measurements to a nonmagnetic metal surface. While magnetic materials could be used, there is a higher initial coupling and a lesser scale factor (change of voltage for change of separation). Displaying appreciable ferromagnetic properties at radio frequencies, an iron or steel base plate superimposes upon the eddy current reduction in coupling a small opposite effect as a consequence of its magnetic permeability. The combined effect is the increased initial coupling and reduced scale factor. As an example, an iron plate might cause a doubled initial coupling and a halved scale factor, so that the per cent change in mutual coupling for a given displacement is one-fourth as large. The greater stability inherently possible with devices displaying large effects makes the use of nonmagnetic surfaces desirable. As the frequency of operation is raised, the performance with iron tends to approach that with copper, but nonmagnetic materials are still preferable.

Almost any nonmagnetic metal which is considered a good conductor of electricity is suitable as a base plate or reference surface. No appreciable difference has been detected between brass and copper, for example. At present, materials of higher resistance have not been fully investigated. At a frequency of three megacycles, a metallic thickness of about 0.001 inch of copper seems to be adequate, and greater thicknesses show no visible difference in initial coupling or scale factor. However, materials having higher resistivity would undoubtedly require somewhat more depth for the same degree of performance. At higher frequencies, the necessary metal thickness is reduced.

The relatively thin layer of copper needed for good performance of this method of electrical distance measurement suggests that it would be advantageous to plate a layer of copper on the surface of magnetic materials to permit precision measurements on iron and steel at reasonably low frequencies. In the oil-film thickness indicator described this is done in order to operate at two to three megacycles. A slightly recessed groove on the steel shaft about one and one-half inches wide is electroplated with copper. This band is centered under the probes, just outside the bearing area. The copper surface is then ground and polished after plating.

Preliminary measurements indicate that the value of indicated distance is substantially independent of the dielectric constant of whatever insulating material is placed between the probe and the metal surface. Even ordinary tap water appears to have no effect. Inasmuch as the probes have to operate immersed in lubricating oil at 200 degrees Fahrenheit, this independence of dielectric constant is a necessary characteristic.

The useful electromagnetic field from the exciting coil (for measurement within the linear range) is closely confined to an area only slightly larger than the coil diameter. No further effect has been observed for increasing diameters of the metal surface above about one and one-half times that of the coil, hence the choice of a one and one-half inch width of copper band for use with the one-inch probe coils. This length of band permits axial motion of the shaft of about one-eighth inch without appreciable detriment to the accuracy of the instrument.

Electrically, this distance-measuring

element may be treated as any two coils having a variable mutual inductance, the transfer characteristic of which may be represented by a single mutual inductance if self-resonance effects are avoided. A mutual inductance bridge could be used for distance measurements, but direct excitation is more generally practicable. When a radio-frequency current is impressed upon the primary, the voltage induced in the secondary is proportional to the primary current, to its frequency, and to the mutual inductance. For a source of given current capabilities, it is desirable to use as high a frequency as possible. However, if the frequency approaches the self-resonant value for the secondary, the output voltage, while substantially increased, becomes dependent upon coil Q, stray capacitances, and critically so of the operating frequency. Obviously, for precision applications, operation near resonance is to be avoided.

Operation at lower than resonant frequency is not alone the solution, as harmonics of the exciting frequency may be accentuated, causing distortion of the linear relation of voltage output with distance. In order to attenuate the resonance rise, a simple low-pass filter, comprising a series resistor working in conjunction with the rectifier shunt capacitance, has been found to reduce it to negligible proportions. Experience has shown that excitation at about one-half the secondary resonant frequency, together with a filter limiting the rise to 50 per cent, is quite satisfactory.

The output of the distance-measuring device may be in the form of a variable amplitude radio-frequency (RF) signal, a d-c voltage, or a low-frequency alternating current. For the first, the probe output is used directly. A diode rectifier is used for the last two. The low-frequency alternating current can be produced by amplitude modulation of the exciting RF current at the frequency desired. Directly indicated measurements of air gaps and insulator thickness require a regulated RF current for excitation of the primary coil, and a diode peak rectifier and d-c voltmeter for the secondary circuit. Regulation of primary current is necessary in order to maintain stability of scale factor in the instrument, since the output readings are proportional to primary excitation. Secondary voltage is rectified by a diode contained in the probe and its output may then be fed to a d-c voltmeter calibrated in distance units.

The output obtainable is limited chiefly by the power dissipation in the primary winding. With a voltage-doubler rectifier, it is easily possible to secure an output in excess of 150 volts direct current for movements of 0.05 inch. This is over three volts per thousandth of an inch, and is a representative value for reasonable excitations, such as can be supplied by one-tube oscillators in continuous-wave operation. If a pulsed RF carrier is applied, with a peak rectifier on the secondary, the output voltage may be raised considerably for equal average primary power. It should be noted, however, that the application of the concentrated electromagnetic field required for high output voltages results in some heating of the base plate. In view of the operating ambient temperature of 200 degrees Fahrenheit at the probes in the bearing test machine, it was felt that an additional few degrees rise at the outer surface of the shaft would be inconsequential

Complete Instrument Assembly

The four probes are mounted on the end of the bearing in positions 90 degrees apart. All leads to the probes pass through a junction box, which also contains the constant-current rectifier. To facilitate removal, the probes are wired from the junction box in two strings of two.

The probe coils are wound on bakelite forms having an outside diameter of one inch and a cross section approximating that shown in Figure 7*C*. These are attached to cored-out steel blocks which also serve as the mounting base. In the

Figure 7. Cross section of several probe coil forms. The average inner diameter is approximately 70 per cent of the outer for all three types. Note larger outer slot in (c).

Figure 8. Schematic wiring diagram for oil film thickness indicator. For simplicity, only one of the four similar probe circuits is shown in detail

Figure 9. The Instrument as Installed on a test sleeve-type bearing. Photographed by United States Naval Engineering Experiment Station

cavity of each block are located the *6AL5* miniature voltage-doubler rectifier and associated resistors and capacitors. The probes are mounted on the bearing housing, overhanging the end of the bearing by about three-quarters of an inch to the center of the coil form. Centered under these is the electroplated copper band. To avoid the possibility of the shaft rubbing on the probe face, the probes are located so that the faces are about 0.010 inch from the shaft when the shaft and bearing are touching. This additional gap is compensated electrically in the calibration procedure.

Since the probe assembly must operate at temperatures in the order of 200 degrees Fahrenheit, the choice of interconnecting wire requires consideration. Glass-insulated wire was finally used, and is protected by temperature-resistant plastic sleeving. The cable from the junction box to the electronic unit is made up of a number of glass-insulated wires inside flexible metal tubing. Excitation power for the probe primaries is fed through a co-axial beaded cable having a short length of temperature resistant shielded lead at the junction box end. The co-axial cable is also located inside the metal tubing.

The electronic unit houses the cathode-ray tube, the oscillator and associated regulator, and the power supply circuits. The cabinet, finished in black wrinkle, is approximately 12 inches wide, 7 inches high, and 18 inches deep. Operation is on ordinary 105- to 125-volt, 60-cycle power lines, with about 80 watts power consumption.

Circuits

The circuit diagram of the oil-film thickness indicator is shown in Figure 8. The essential elements are the radio frequency oscillator, the regulator for holding constant RF output current, and the cathode-ray tube. The power generation circuit consists of an oscillator at 2.5 megacycles, using an 807 beam power tube. The necessary oscillation feedback from plate to grid is provided by a step-down transformer in the instrument. To supply as much power as possible to the exciting coil and to reduce the number of tuned elements, the exciting winding is made part of the oscillator plate tank coil itself. Directly in series with the exciting coil is a current transformer for obtaining an indication of output current. Since its output current, rather than voltage, is monitored, changes in lead length and resistance of the windings have negligible effect upon the magnitude of the probe coil outputs. The combination of exciting coil and low voltage winding on the current transformer is parallel-resonated by the tank condenser, so that the tube itself has to supply only a small fraction of the current in the load. In this instance the Q is in the order of 20. Most of the losses causing such a relatively low Q arises from the close proximity of the exciting coils to the copper-plated band on the shaft. Approximately half, or 250 micromicrofarads, of the tuning capacitance is that of the cable between the electronic unit and the probe coils.

The current transformer has sufficient step up in its turn ratio that 165 volts direct current is obtained from a full-wave doubler rectifier contained in the probe junction box. The d-c output is compared to a negative reference potential by a precision voltage divider, with the difference being fed to a direct coupled amplifier. Through a cathode follower, this controls the screen grid voltage on the power oscillator. The result is that the oscillator output current is regulated very closely to the negative reference potential.

The cathode ray tube, with its four deflection elements in quadrature, is ideally suited for displaying the polar diagram of radial shaft displacement. However, the sensitivity of an electrostatic deflection type of tube is inversely proportional to the second anode accelerating voltage; that is, the voltage required for a given deflection is proportional to the accelerating voltage. Now if the oscillator output is regulated to follow the variations of anode accelerating potential, a rise in this potential will cause a similar rise in probe output, so that the deflection remains constant. In this manner, the necessity for regulation of second anode potential of the cathode ray tube is obviated.

The oscillator control circuit has high gain in order to provide extreme constancy of deflection. If the regulator feed-back loop is broken, and a small voltage change introduced into the circuit in a forward direction, this increment appears amplified 200 to 300 times at the other side of the break. This may be considered as the figure of loop gain for the circuit. Effects due to supply voltage variations and the like are attenuated by this factor.

The probe secondary circuit comprises the low-pass filter resistor and the full-wave voltage doubler rectifier. A dual diode *6AL5* is used in each probe. The rectifier output is fed back to the electronic unit where a controllable d-c bucking voltage is introduced for zero adjustment. The difference is proportional to the spacing from bearing wall to shaft surface, when properly set. Since all probes are not exactly similar, and since deflection sensitivities on cathode ray tube plates differ, scale factor controls in the form of potentiometers are inserted between the difference voltage terminals and the deflection plates. The zero and scale factor controls are located on the front panel, and are slotted for rotation with a screw-driver.

Calibration

A selector switch permits examination of each probe alone, as well as of the combination of all four. The individual positions are used in the calibration procedure, while the normal operating position is with all four probes connected to the deflection plates.

Calibration of the instrument is quite simple, although provision must be made in the bearing mounting to move the shaft in the bearing by means of a hoist or jacks. The shaft is held against the bearing wall immediately under each probe in turn. The zero-set control for each probe is then adjusted so that the spot on the cathode ray tube is at the center of the screen. Since the shaft-

bearing clearance is known precisely from micrometer measurements, this figure will be the spacing between shaft and bearing at the location diametrically across from the point of contact of shaft and bearing. The scale factor control of the probe across from the point of contact is therefore set for the proper reading on the rotatable scale. As discussed before, the single probe deflection factor is one-half, so that the control is manipulated for an indication of one-half this total clearance. When these adjustments have been made for all four probes, the instrument is completely calibrated.

The two other positions on the selector switch should be mentioned. The counterclockwise stop disconnects all deflection circuits and ties the plates to ground, with the result that the spot then lies at its undeflected position. This must coincide with the center of the rotatable and angular scales on the front panel. Four screws projecting inward through the bezel rim on the panel serve as adjustable clamps for the screen end of the tube. The range of adjustment is normally sufficient to take care of tube to tube differences in undeflected spot position.

The extreme clockwise position of the switch adds a capacitor to each of the deflection circuits of the cathode ray tube. Its purpose is to remove vibratory components of displacement, in order to ascertain true average shaft displacement.

Performance

Figure 9 shows the instrument as used for oil film measurements on a test sleeve bearing. Three of the four probes and the junction box may be seen mounted in place around the shaft. The location of the junction box is determined largely by convenience and the length of the leads to the probes. On the panel of the instrument may be seen the calibrating controls, accessible by a screwdriver, and the cathode ray tube screen. The angular scale is visible around the periphery of the tube screen.

At the date of writing, not a great deal of test data on bearings is available. The machine for which the oil film thickness indicator was designed has displayed very little vibration, with the result that changes in load simply cause the spot to shift to a new location and remain motionless. Photographic recording appears unnecessary. Vibratory conditions have been set up in dummy shafts however, and from qualitative observations appear to be satisfactorily reproduced. The effective bandwidth of the probe outputs is in the order of 2,000 cycles per second, so that the higher frequency components of vibration can be included in the presentation.

Reliable figures of accuracy are not yet available and indeed would be hard to secure. During the first tests of the equipment, it was found that the loop gain of the regulator circuit was inadequate to compensate completely for the temperature change in copper resistance of the coils. The calculated change is about 35 per cent; this causes a corresponding decrease in coil Q, necessitating a higher oscillator screen grid voltage. It was at this time that the present step-up current transformer was introduced. The increased loop gain brought the over-all change at 220 degrees Fahrenheit down to a value equivalent to less than 0.0002 inch inward motion of the probes.

Due to the use of a bakelite coil form, there is an actual inward motion of the probes when subjected to the elevated temperatures. The thermal expansion of bakelite, being higher than that of steel, gives rise to a differential expansion of about 0.0003 inch.

The combination of these two sources of error is approximately one-half thousandth of an inch. Experiments now in progress indicate that this change may be compensated to a considerable extent by employment of a temperature sensitive resistor as a part of the scale factor control circuits in the junction box. However, all probes are not at the same temperature. There appear to be other anomalous variations, all of which, together, lead to an assumption of an over-all accuracy figure of better than 0.0005 inch.

Discussion

J. F. Kalbach (Scientific Laboratory, University of California, Los Alamos, New Mexico): In describing a tool for obtaining new fundamental data on bearing operation, M. L. Greenough has provided another example of how electrical techniques can assist developments in many diverse fields.

If the oil film thickness indicator, as described, is used to study shaft vibrations, the closed loop observed upon the oscilloscope screen will represent the motion of the shaft relative to the bearing housing. In many instances, however, the bearing housing is not absolutely rigid, and is a part of the vibrating system. In such instances, there may be some advantage to mounting additional probe coils on a substantial support isolated from the bearing housing. This arrangement would give an indication of shaft motion in space which is desirable for checking vibration calculations.

It might also be pointed out that the oscilloscope circuit could be easily modified so that spot brilliance could be modulated at a suitable adjustable frequency. The closed loop of the oscilloscope trace would then be broken into a series of dashes by timing marks which would be useful for computing the velocity of shaft movement at any point along its vibrational path.

M. L. Greenough: In connection with Kalbach's remarks, it should be mentioned that this instrument was specifically designed to measure oil film thickness, and incidentally, any attendant vibration, since the interest was in shaft to bearing clearances.

A mutual inductance micrometer which was set up for noncontacting vibration indication showed the feasibility of using the device for such measurements, however. The frequency bandwidth of vibrations which may be measured is limited only by the time constants of the rectifier filter circuits, since the micrometer is driven at a carrier frequency of several megacycles.

Time marks obtained by blanking of the cathode ray tube beam would be quite useful when photographic recording is desired. To avoid overlapping of succeeding traces and resulting confusion, the length of exposure time must be the same as the complete period of the vibration pattern.

Power Costs and the Contribution of Existing Transmission Networks Towards Cost Reduction of Power for Electrification of Main Line Railroads with Moderate Traffic

LLEWELLYN EVANS
FELLOW AIEE

Introduction and Conclusions

THIS PAPER is one of a symposium on the subject of electrification of main line railroads having medium traffic and depends on a paper by R. L. Kimball and J. G. Holm[1] on the subject of railroad electrification energy conversion and transmission costs for a full description of the railroad and the electric equipment. The symposium gathers the facts and costs on the premise that main line railroad electrification can profitably be extended to include medium traffic railroads and should not necessarily be confined to the field of heavy traffic and heavy grades. Power costs are the theme of this paper which sets up and distributes the estimated electricity requirements and computes the bills for the four conditions covered by the Kimball-Holm paper; namely, a-c 25-cycle scheme with 1940 traffic as 100 per cent and present traffic as 157 per cent of normal, and like estimates for a d-c system. The results show that the total cost of power is of the same order as the capital charges for the trackside construction and substation as predicted by Kimball and Holm,[1] but the average price for power varies from 0.5 cent to 2 cents per kilowatt hour, depending on the load factor of the individual stations and the source of power. Conditions such as regenerative braking on grades, careful dispatching of trains, and so forth, can be chosen so as to earn a desirable price for power. The annual cost of building and operating transmission lines to combine metering stations is more than twice as much as the extra demand charges at the supply points.

To make realistic a set of conditions to go with the companion paper, the 330-mile double track railroad in the Kimball and Holm paper[1] has been set down so as to traverse the territory of three utilities with power connections assumed at four stations for alternating current, or six stations for d-c supply. The trains run with the following travel pattern: "For 100 per cent traffic, each of these fleets consists of four trains, and for 157 per cent, of five trains." In both the cases the spacing between trains is eighteen miles and the fleets are preceded and followed by uniform train movements every forty miles; thus "bunching" of trains for the two traffic levels takes place over 54 and 72 miles respectively. The demands per train at 25 cycles alternating current are 7,500 kw *A* to *D* (see Figure 1), and 5,000 kw *D* to *F*; and for d-c power to trains, 7,040 *A* to *D* and 5,000 *D* to *F*. Two traffic levels are assumed, 6,065,000,000 ton miles, 100 per cent for 1940 and 157 per cent of this amount for the current traffic level. The power requirement has been estimated at 37,000 kilowatt-hours per million ton miles with 12 per cent added for locomotives. The kilowatt-hours are distributed between stations by allowing for the grades and the speeds and according to the number of miles

Table I. Summary of Estimated Power Bills, Unit Prices and Load Factors

	A-C 100 Per Cent Traffic	A-C 157 Per Cent Traffic	D-C 100 Per Cent Traffic	D-C 157 Per Cent Traffic
With No Diversity Between Trains				
Total power bills	2,541,084	3,419,100	2,811,444	3,568,728
Energy charges	1,046,604	1,634,580	1,054,044	1,666,848
Demand charges	1,494,480	1,784,520	1,757,400	1,901,880
Total kilowatt hours (1,000s)	218,269	342,672	206,172	323,712
Sum of the station demands	127,000	146,600	142,900	153,500
Sum of station demands for maximum month	159,000	183,000	178,900	191,500
Average monthly simultaneous demand	112,000	124,000	100,000	116,000
Maximum monthly simultaneous demand	140,000	155,000	130,000	145,500
Average price per kwhr, cents	1.165	0.997	1.365	1.101

Load factor based on simultaneous demands	44.5	63.3	43.2	63.7

Paper 48-97, recommended by the AIEE land transportation committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 11, 1947; made available for printing December 2, 1947.

LLEWELLYN EVANS is chief consulting electrical engineer of the Tennessee Valley Authority, Chattanooga, Tenn.

R. B. George, electrical engineer for TVA, had made several studies of the railroad electrification problems in the Southeast and was good enough to read this paper and make some useful comments. O. S. Wessel checked computations in some of the cases of the paper. R. L. Kimball and J. G. Holm have given us the benefit of their judgment on the choice of some assumptions. We have been collecting railroad electrification data for some years at our TVA office, and these files have been used freely.

Table II. Estimated Power Bills for A-C and D-C 330-Mile Electrified Railroad at 1940 Traffic Level, 100 Per Cent, and at 157 Per Cent

Stations *A*, *C*, and *a*, *b*, *c* Are Supplied by a Hydro Network
Stations *E* and *d*, *e*, by a Small Steam Network
Stations *F* and *f* by a Large Steam Network

* Bottom limit for two trains.

included halfway to the next station. The demands have been arrived at by bunching the trains at each station successively and dividing the loads between stations inversely proportional to the distance. To give as high a load factor as practical to each station, the load has been limited by shifting to other stations to the extent that adjacent stations could carry the overflow. To this reduced load, 2,500 kw was added for tolerance in governing at a-c station and 1,666 kw for direct current. Two situations have been considered and monthly bills computed for 100 per cent and 157 per cent traffic for both a-c and d-c systems.

The first tabulation assumed that all the trains were running full loaded all the time, while the second is an estimated bill with a diversity of two between trains. The last diversity assumption provides for trains standing on sidings, going down grade, and traveling partly loaded.

In distributing the kilowatt-hours and demands over the months of the year, the highest consumption has been taken at 150 per cent of average and the lowest at 50 per cent of average month, while the highest demand has been estimated as 125 per cent of average and the lowest at 75 per cent of average. A demand of 80 per cent of maximum and a consumption of one twelfth of the annual kilowatt-hours proved to be a medium bill for reducing the work of computation.

The rate schedules chosen are taken from the Federal Power Commission's compilation and are the lowest applicable rate published in each territory where metering stations are assumed to feed the railroad from the utility networks. For stations *A*, *C*, and *a*, *b*, *c* (see Figure 1), the demand charge is 90 cents a kilowatt and the energy charge 0.25 cents per kilowatt-hour. At stations *E* and *d*, *e*, the demand charge is $1.25 and the energy charge 0.8 cent per kilowatt-hour. At stations *F* and *f*, the demand charge is $1.00 and the energy charge 0.7 cent for first 120 hours use of the demand and 0.5 cent for the remainder. In all three schedules the small blocks and items which do not apply are not listed. These items affect the result less than one per cent but nevertheless have been computed in arriving at the figures in Tables I, II, and III.

Combining stations has no merit. Comparative estimates are made as follows: By joining *a*, *b*, *c* metering points with a transmission line, the reduction in demand cost would be the difference in demand charges for simultaneous and separate demands. In the 100 per cent d-c case without diversity, this is 13,305 kw at 10.80 a year or $133,094; and by

Figure 1

combining *e*, *f*, *d*, 4,177 kw at 15, or $62,650, making a total of $195,744 a year. It would take 120 miles of 100 kv line in each case costing $2,400,000 plus 70,000 kw capacity of high voltage substation capacity in each case, costing $1,400,000, total investment $3,800,000 for which the annual charges and operation would be $380,000, indicating positive advantage in buying power along the railroad from utility networks at advantageous points. A study of the tabulated cases and the rate curves shows sharp penalities for low-load factors. The annual bill drops from $3,568,728 at 20.5 per cent down to $2,717,892 at 48.8 per cent in the d-c 157 per cent cases.

The cases for which prices are computed cover a range which makes it possible to calculate by proportion the costs for others.

The most likely operating conditions on the 330-mile road in question, indicate an annual cost of $1,823,376 at an average rate of 0.884 cent per kilowatt-hour for 100 per cent traffic and $2,471,028 with an average rate of 0.686 cent per kilowatt-hour at 157 per cent of traffic. Possibly 10 per cent lower costs could be earned by careful dispatching and locomotive operation. Much higher costs could also result from train schedules and dispatching which disregard system peaks.

The problems of power contracts and rates are covered in AIEE literature.[2,3]

Discussion

T. M. C. Martin (Bonneville Power Administration, Portland, Ore.): Tables I and II and Figures 1 and 2* of the discussion comprise a brief analysis of the author's paper and the paper by Kimball and Holm.[1] This analysis is based on average monthly data applicable to the 330-mile section of railroad set up by Kimball and Holm. Unlike their paper, however, this analysis will, for convenience of calculation, assume that freight traffic is balanced by direction. This is not a major change since their paper assumed only a slight difference in eastbound and westbound tonnage. The total annual freight traffic mentioned in the subject papers (for their 100 per cent traffic case only) was given as 5,118,500 thousands of gross ton miles, and passenger traffic on the same basis was given as 947,000 thousands of gross ton miles. This is equivalent to the following average daily traffic, including movements in both directions:

Freight.....42,500 gross tons trailing
Passenger.....7,860 gross tons trailing

It was stated that although this was supposed to be a railroad of "moderate" traffic density that trains would be "fleeted" in both directions, presumably simultaneously, and although not specifically stated, it is believed that the intention was to have this "fleeting" operation apply to both passenger and freight trains. It seems impossible to account for peak demands of the magnitude shown in Evans' paper in any other way.

Accepting the principle of "fleeting" as stated before, Figure 1 of the discussion was prepared. Some locomotive had to be assumed and the one selected was the Great Northern's *5018 class*, but geared for 75 miles per hour top speed and a continuous speed of about 17 miles per hour. By using two of these units on maximum tonnage freight trains, and by running over the line at the speeds used by Kimball and Holm, it was possible to account for a peak demand of about the same magnitude as calculated by Evans. It should be noted, however, that this is fleeting with a vengeance. The average daily energy requirements for this method of operation are 673,560 kilowatt-hours, the simultaneous peak demand is 127,740 kilowatts and the load factor therefore about 22.0 per cent.

To illustrate what can be done with a little less fleeting, Figure 2 of the discussion was prepared. Two important operating changes were made:

1. Freight trains were slowed down somewhat on the ruling grade in order to permit a better locomotive tonnage rating.

2. Passenger trains though fleeted in both directions were not dispatched simultaneously from both ends of the section.

It was found possible to take all the freight tons to be moved in ten trains each of 4,250 gross tons trailing with one 360 ton locomotive. These trains were spaced out on a reasonable basis through the day. The result is to reduce the peak demand to 40,300 kilowatts and raise the load factor to 58.2 per cent.

The advantages of operations patterned along the scheme of Figure 2 of the discussion, are obvious so far as the power supplier is concerned. It is believed that the matter doesn't end there however. It seems doubtful if any railroad would be justified in committing itself to an operation of the kind represented in Figure 1 of the discussion. This would be true whether the motive power were electric, diesel-electric, steam, or any other kind. Based on average daily traffic it is evident that 28 Great Northern *5018 class* locomotives would be required to handle the assignments of Figure 1, while 12 of exactly the same kind of locomotives would provide equal protection for the assignments of Figure 2. Further, if the section is to be electrically operated it is obvious that there is a wide difference in the cost of frequency changer stations and trackside substations between the two plans of operation. It may be doubted that many railroads with the kind of traffic contemplated here can indulge in fleeting operations of this sort. They generally lack track capacity and yard facilities to enable such concentrations of activity, with their attendant bottlenecks of all kinds even if they could afford the lush supply of substation capacity and motive power which would be required.

The foregoing analysis is not meant to prove that Figure 2 of the discussion represents the way to do the job. What is intended is the suggestion that the interests of power suppliers and railroads do not run quite so contrary as might be inferred from Figure 1. It seems fair to conclude that a railroad with but a moderate traffic density need not foreclose all likelihood of achieving a good power rate by insistence upon a fleeting operation of maximum tonnage freight trains that is inconsistent with the best interests of its power suppliers and of largely illusory value to itself. Based upon

* Computations for the tables and figure of this analysis are only approximate. A slide rule was utilized freely and many quantities were rounded off to nearest hundreds and thousands. Train shoots were greatly simplified and idealized.

Figure 1. Profile train sheet and substation load chart for analysis basis number 1

Figure 2. Profile train sheet and substation load chart for analysis basis number 2

western observations, it is believed that an electrification extending over 330 miles of profile similar to that assumed in the Evans and Kimball and Holm papers would easily handle the assumed traffic with an installation totalling not more than 50 per cent of the installed frequency changer and track-side substation capacity contemplated in these papers. Likewise it is believed that traffic of this density should produce an electrical load factor on an average monthly basis of at least 45 per cent without sacrificing any flexibility of operation that the railroad could reasonably and efficiently utilize. And, as pointed out earlier, this could be accomplished with a saving of at least 50 per cent in the required investment in motive power, a consideration that is not inconsequential.

H. F. Brown (New York, New Haven and Hartford Railroad, New Haven, Conn.): In Table I of the paper Evans shows the effect on load factor by an assumed traffic diversity. Many factors control the ability to spread out railroad load. Some lines have definite daily markets to meet with their freight trains. Others, like "coal" roads, can schedule their trains to make a very uniform traffic flow. The net effect, as the table shows, is only to reduce demand charges for electric power.

Another author, J. F. N. Gaynor,[1] has pointed out the very restrictive effects of demand charges on electric power costs. It would seem equitable, if large power developments really desire the railroad base load, to work out lower demand charges which would take more into consideration the diversity between the railroads' demands and the power system peaks, allowing the railroads to have a certain proportion of the off-peak load, and at night, when normal industrial demands are at a minimum, without such restrictive demand charges, just as household water heating is encouraged by some electric utilities to build up their load factor.

The railroads are utilities, just as are power supply systems, and both being public servants should be able to work out such problems together in the interests of better public service, as well as to their mutual benefit.

Exploring further the unit costs of power presented by the author in Table I of the paper, and plotting on the power cost chart (Figure 1 of the paper) the average cost per kilowatt-hour for the load factors shown, for both diversities and for both types of electrification, it will be found that the unit costs of d-c power fall on a curve about 1 mil above curve *B* (Large Steam Power System Rate), and the a-c unit costs fall on a curve almost coincidental with curve *B*, except for load factors of 30 per cent or below, where they drop slightly below curve *B*.

This does not indicate that the "Large Water Power System Rate," has a very great effect on the proposed electrification power costs; and does seem to indicate that, in general, large hydro developments (especially those made at the expense of public funds) are not usually located where industry or transportation can use their output; or if their output can be so utilized, the hydro stations must be largely backed-up by steam stations, which determine the rates.

If the unit costs shown are due to conversion costs, then my comments on such made in connection with the paper by Kimball and Holm[2] are pertinent.

lated that the railroad purchases power from three separate public utilities. As a result, the railroad has three separate power contracts and must pay for the purchased power at varying rates. Moreover, the power schedules chosen indicate that at low-load factors the rates are very unfavorable. It is reasonable to assume that such a railroad would have to deal with several sources of power supply at varying rates. However, the railroad would strive for uniformity in power contracts, if not for entirely uniform power rates, and has powerful arguments to use in these negotiations. Assuming that the power companies are not directly interconnected with transmission lines, in supplying power to the railroad they may be interchanging power to a certain extent through the railroad circuits. This situation might lead to an agreement between them resulting in more uniform rates to the railroad. It should be borne in mind that an electric railroad is a large and steady power customer, and there is always the possibility that it might erect its own power plant. These factors would tend to cause the public utilities involved to arrange between themselves for the interflow of power supplied to the railroad. Highly advantageous operating conditions could be obtained for the power companies, and rates might be secured for the railroad that are more uniform and more economical than those assumed by Evans.

If my understanding of the author's figures is correct, Evans calculated his load factors for the sum of the maximum peaks at each station. These, however, do not actually occur simultaneously. If the calculation of load factors was made on this basis, it may be favorable to the public utility, but results in less favorable rates to the railroad.

The method of determining the demand charges also has a bearing on the final cost per kilowatt-hour of purchased power to the railroad. It is not quite clear in Evans' paper whether the demand charge is taken for the sum of individual station demands for a maximum month, or for the average monthly simultaneous demand. It seems to me that the diversity factor 2 should be applicable to the average demand rather than to the maximum demand, otherwise the calculation of total demand charges might be high.

The question of power requirement for tonnage moved is important. Evans estimated it to be 37,000 kilowatt-hours per million gross ton-miles. Although this figure is quite representative, it must be pointed out that it varies greatly on existing railroads. On one railroad, for instance, the figure is considerably greater and on another railroad in the same area it is smaller than the figure assumed in the paper. A higher power requirement should unquestionably result in lower power rates.

Finally, one more point is of importance. Evans' objective was to calculate the cost of power as delivered at the locomotive. He considered separately the d-c and the a-c electrifications. The Kimball and Holm paper, however, considers direct current and two types of a-c locomotives: one operating at an 85 per cent lagging power factor and the other at 95 per cent leading power factor. The latter locomotive relieving the power-supply system of reactive load would have certain beneficial effects which might result in somewhat more favorable power rates.

When all the factors discussed are properly considered, the economy of an a-c or a d-c electrified railroad handling medium volume of traffic may show up to even greater advantage than indicated in Evans' interesting paper.

Llewellyn Evans: To answer Holm's and Brown's questions in regard to method of arriving at the demands at each station; the average billing demand used was 80 per cent of the demand for the highest month. The maximum demand was arrived at by spacing the trains in fleets (as proposed in the Kimball and Holm paper) with the trains 18 miles apart and followed by trains 40 miles apart. The load arriving at the meter of any station was a composite of the fully loaded locomotives on either side of the station divided inversely proportional to the miles between the train and the stations. The peak was investigated for all parts of the schedule and an allowance made for possible errors of operation. These demands resulted in figures shown in Table II of the paper, and figures shown in Table III are the result of dividing the demand for the average month by two.

Answering T. M. C. Martin's discussion, I have figured the bills for his time table on the same schedule but without the tolerances or diversities and the results have

	40,300 kw (Simultaneous)						60.

totaled 4 per cent cheaper than those of Table III, so that the method of arriving at probable power costs are fairly close to those arrived at by the more complete scheme of making a schedule and figuring the load for each grade and stretch of track.

In assuming that the railroad would buy from the power companies along its route, we have been realistic. An examination will show that the plan of distribution and transmission proposed by Kimball and Holm has a tendency to minimize any extra cost due to metering at four separate stations because the distance between stations, especially in the a-c case, is great enough to allow for the effect of diversity between trains and the voltage is high enough to permit shifting the load from any one station to the adjacent station. In fact, the railroad operator could fix an automatic limit to the demand at each station and allow any excess to spill over to adjacent stations. As a clarification of the method of figuring the power bills, I am including a twelve month's computation (Table IV of the discussion). This table contains the month by month bills for station *C* for 157 per cent traffic on the a-c system, the average month of which is shown on Table II of the paper.

To answer Holm's request for power costs for 95 per cent leading power factor locomotives, I have prepared Table III from Martin's discussion of my paper from the data in Tables I and II and Figure 2, of his paper. Inasmuch as Martin was using motor-generator set locomotives, the power requirements are of the same order.

H. F. Brown has properly raised the question of mutually negotiated contracts between the railroads utility and power utility. The schedule used in Martin's discussion shows that the time of peak on the service stations were:

E	2:00 a.m.	18,745
C	3:00 a.m.	13,614
A	4:45 a.m.	14,250
F	5:00 p.m.	12,810

A load of this kind that entirely escapes the utilities important peaks could have earned demand charges lower than those in the published schedules used in my calculations. Philip Torchio in his paper "Railway Power Supply,"[1] has covered the matter of contracts for railroad supply and I avoided duplicating this work. In a verbal discussion, H. F. Brown raised the question of the power utilities furnishing the converter stations. In special instances this also might be negotiated to the advantage of both utilities because:

(1) The motor of the frequency changer can often be used to supply condenser capacity.

(2) There are often supply points on utility systems where the 13-kv level can be used directly to supply frequency changers and save the cost of one set of transformers provided for in the Kimball and Holm estimate.

It is true that most of the large water power system rates are available at a distance from large industrial and transportation centers but there are numerous instances where railroads of intermediate traffic (about 4,000 miles of them) such as is under discussion traverse the area where such power is available at least for part of the road distance as supposed in this paper.

The detailed schedules and computations provided in Martin's discussion closely follow the probable operation of the section of line selected for study. Accordingly, I have in Table III of the discussion computed the power costs in such a fashion that they are directly comparable with Table III of the paper. The demands and consumption of the various track sections listed in Martin's Tables I and II of the discussion have been shifted to stations *A*, *C*, *E*, and *F* of the original paper. The demands were arrived at by following the schedule of Figure 2 in the Martin discussion paper. The same method (as in Table III) of proportioning the load to each station inversely as the distance from the train to the station was used. No tolerance amounts were added and no diversity applied because the method used by Martin for computing the power requirements are actually fitted to a schedule and grade. The computation of power costs show a substantial improvement in the load factor based on simultaneous demand but only 4 per cent saving in total cost. Probably in actual operation the railroad could operate to still better advantage by shifting part of the demand from station *E* to the stations on either side where the power costs are lower. As it stands the theoretical saving is not as great as might be expected largely because (1) of billing from four separate stations instead of one as supposed in Martin's discussion, (2) Martin scheduled the greatest load for station *E* which happened to have the highest rates.

In the original paper and the discussions, we have uncovered the extremes in power costs. There seems to be a very favorable opportunity for negotiating an economic power supply in a situation such as has been studied in these papers and discussions. I appreciate that the discussions have added greatly to the value of the original paper and feel repaid for having made the effort to produce a part of the symposium.

Table IV. Estimated Power Bills for Station C

157 Per Cent of 1940 Traffic With a Diversity of 2.0, A-C System, 330-Mile Electrified Railroad

The Liquid Rheostat for Speed Control of Wound Rotor Induction Motors

G. L. McFARLAND
MEMBER AIEE

W. ALVAREZ
NONMEMBER AIEE

Scope

THE widest application of the liquid rheostat is for acceleration and speed adjustment of wound rotor induction motors. Modern wind tunnel drives, centrifugal pump and fan drives and steel mill roll drives are among those applications depending upon the liquid rheostat for speed control.

Although liquid rheostats have been applied for many years, there have been surprisingly few technical articles written describing the basic design and features of these devices. This paper has been written to acquaint the reader with the basic design of modern liquid rheostats and the basic data on types of loads and control systems.

Basic Design

Speed control systems using the liquid rheostat are noteworthy for their stepless speed control, minimum maintenance and maximum dependability. Most applications in recent years have been installations for motors ranging from 1,000 to 30,000 horsepower.

Figure 1 shows a typical rheostat design for speed adjustment of a 29,000 horsepower 3-phase wound rotor induction motor for a wind tunnel drive. This particular rheostat is approximately 18 feet high, 12 feet wide, and 7½ feet deep. Figure 2 is a rear view, showing the three separate tanks, one for each phase. The motor secondary cables are bolted to the terminal strips below each tank.

Figure 3 shows a liquid rheostat for a 9,000 horsepower motor. This particular rheostat is 15 feet high, 8 feet wide, and 5 feet deep. Electrodes for all three phases are mounted in a single tank.

Basically, the liquid rheostat consists of metal electrodes in a tank of electrolyte, usually a solution of a few per cent of sodium carbonate by weight in clean water. The sodium carbonate used should not contain more than 1/2 per cent of sodium chloride or sodium sulfate or more than 1 per cent of sodium bicarbonate if maximum electrode life is to be expected.

Current flows between the electrodes through the electrolyte, the resistance between electrodes being approximately proportional to the distance between them.

To insulate the stationary electrodes from the steel tank and from each other, an insulating cell is used around each pair of electrodes. Cell construction is typified as open cell or closed cell construction. The closed cell design is used when a high value of resistance per phase is required at maximum electrode spacings, such as for centrifugal fan, pump, and compressor load applications. The open cell design is used where relatively low resistances per phase are required, as for constant torque loads. Smooth speed control is obtained by varying the resistance in each phase of the motor secondary, the resistance being varied by raising or lowering the movable electrode.

Figure 4 shows a schematic drawing illustrating the internal design of a liquid rheostat in which the three insulating cells are mounted in one electrolyte tank. Details of the closed cell construction are shown in Figure 5. Resilient gaskets between the insulator and the steel tank prevent leakage of the electrolyte. Inlet pipes, which introduce electrolyte beneath the lower electrode, are made from hard rubber as they must not short circuit the resistance path between the electrodes. For electrodes up to 10 inches in diameter, cells are made from a ceramic material. For larger sizes, rubber coated steel cells are used for greater strength.

Figure 6 shows the open cell design in which circulation ports near the lower electrodes allow the electrolyte to circulate up through the cell and out over the cooling coils by thermal convection. Phase insulation between cells is required to prevent excessive current leakage between the stationary electrodes.

Since the resistance of the rheostat is to be easily changed, the movable electrode assembly is connected to an operating mechanism of some kind. These mechanisms may be:

1. Pilot motor.
2. Torque motor.
3. Air cylinder.
4. Hydraulic cylinder.
5. Manual device.

The movable electrodes are partly counterbalanced with weights to minimize the power required to move them.

The power loss in the electrolyte between electrodes is instantly absorbed by the electrolyte itself, thus raising its temperature in the portion carrying current. The horsepower dissipation rating of the rheostat then depends upon the means for cooling the electrolyte.

The open cell design takes advantage of the natural convection created by differences in electrolyte temperature. Cooling coils are generally used directly in the rheostat tank itself, the heat being removed by cooling water. This usually results in the lowest rheostat cost, although it will not be a minimum size.

Where closed cells are used, the electrolyte is pumped to the bottom of the cell beneath the lower electrode to insure positive circulation. Since an electrolyte pump is used, the electrolyte is forced through a liquid-to-liquid heat exchanger

Paper 48-98, recommended by the AIEE industrial control committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 28, 1947; made available for printing December 19, 1947.

G. L. McFarland and W. Alvarez are both with the control engineering division of the apparatus department, General Electric Company, Schenectady, N. Y.

outside the rheostat. This results in the smallest over-all size of device and has the advantage that the external heat exchanger can be cleaned very easily when necessary.

Resistance properties of the electrolyte depend upon the concentration of sodium carbonate in the electrolyte and upon the temperature of the solution. Figure 7 shows the variation in resistance due to these two factors. From the curves, the resistance at 65 degrees centigrade is roughly 50 per cent of the resistance at 20 degrees centigrade. In other words, the electrolyte has a negative temperature coefficient of resistance. Resistance between electrodes also depends upon the current density existing at the electrode surface. (See Figure 8.) Resistance is decreased approximately 8 to 14 per cent when the current density is increased from 3 to 10 amperes per square inch of electrode area.

These resistance variations of the electrolyte do not present any problems in rheostat operation, however, as the electrodes are easily moved to the desired resistance setting.

Figure 9 shows a piping layout of a typical installation with external coolers. Since the circulating pump for the elec-

trolyte always operates with a positive suction head, no air pockets can accumulate in the piping system at any point. Sump tanks are not required for successful operation of the rheostat. The over-temperature relay provides protection against excessive electrolyte temperatures. To keep the cooling water flow to a minimum, a temperature control valve, regulating the flow of cooling water, is used to maintain constant electrolyte temperature for all values of horsepower dissipation.

For any given horsepower dissipation, the electrolyte flow depends entirely upon what difference in electrolyte temperatures can be allowed. Figure 10 shows that minimum electrolyte temperature differential is obtained by maximum electrolyte flow. The electrolyte pump must provide 11.3 gallons per minute per 100 horsepower dissipation to limit the outgoing electrolyte temperature to 65 degrees centigrade when the electrolyte inlet temperature is 40 degrees centigrade.

Makeup water is required to maintain constant electrolyte level as slight evaporation and hydrolysis occur. As in the case of the water originally used to fill the tank, makeup water should be clean and suitable for drinking purposes.

Motor Characteristics

For the sake of clarity, the convenient per unit system of expressing physical quantities is used, and the internal rotor circuit resistance of the motor is neglected. The term "rotor circuit resistance" used frequently in the discussion therefore includes only the resistance in the liquid rheostat, unless otherwise specified.

Figure 11 shows typical motor speed-torque curves: *A-B-R1-H*, *A-D-R2*, and *A-F-K-R3* for corresponding values of rotor circuit resistance, which are read directly at point *R1* (0.63), point *R2* (1.0), and point *R3* (2.0), respectively. Similarly, other motor speed-torque curves may be plotted for other desired values of rotor circuit resistance. These speed-torque curves may be assumed to be straight lines over the torque range indicated on Figure 11.

Load Characteristics

Centrifugal Pump and Fan Loads. A common type of load characteristic is that

Figure 8 (left). Properties of sodium carbonate electrolyte—variation of resistance with current density

Figure 10. Horsepower dissipation and electrolyte flow requirements for various electrolyte temperature differential

provided by centrifugal fans, pumps, and compressors. This type of load, in an ideal sense, is classified by the relationship, "the load torque varies as the square of the speed," that is,

$$T = 1.0N^2$$

This load characteristic is illustrated in Figure 11 by curve *O-B-D-F-M*.

To illustrate the use of Figure 11, assume that the motor is at standstill and that the rotor circuit resistance is selected. At $R=2.0$, read at point *R3*. At the instant rated voltage is applied to the motor, the stalled motor torque is read at point *K*, $T=0.5$ at $N=0$. The initial current at standstill is also read at point *K*, $I=0.5$. The motor accelerates from standstill at point *K* along curve *K-F* to point *F*, where the speed reaches a steady-state value $N=0.5$ with $T=0.25$ and $I=0.25$. Reading vertically up from point *F* to point *G*, the slip is observed to be, $S=0.5$.

Similarly, selecting $R=1.0$ at point *R2*, the stalled motor torque is read at point *R2* ($T=1.0$, $I=1.0$). The motor accelerates from point *R2* along curve *R2-D* to point *D*, where the final operating speed is $N=0.62$, with $S=0.38$, $T=0.38$, and $I=0.38$.

Where $T=1.0N^2$, the rotor circuit resistance per phase, R, required to give any steady-state operating speed, N, may be derived as follows: From Figure 11, at point *F*:

$$\tan\varphi = \frac{T_F}{1.0-N_F} = \frac{N_F^2}{1-N_F} \quad \text{since } T_F = 1.0N_F^2 \qquad (1)$$

$$\text{Also, from Figure 11 } \tan\varphi = \frac{1.0}{R_3} \qquad (2)$$

where R_3 is the resistance value intercepted by motor characteristic *A-F-K-R3*.

Solving for R_3 in equation 2, substituting the expression for $\tan\varphi$ given by equation 1, and generalizing the resulting expression, we obtain,

$$R = \frac{S}{N^2} \text{ where } S = 1-N \qquad (3)$$

This expression for R is plotted in Figure 12 and it shows that large values of resist-

Figure 9. Piping diagram for liquid rheostat with external heat exchanger

Figure 11. Motor speed-torque characteristics

Figure 12. Resistance versus speed for a load torque $T=1.0N^2$

ance are required to obtain low operating speeds. For example, referring to Figure 12, to obtain operation at $N=0.1$ or 10 per cent speed, $R=90$. If the per unit value of R is, say, 1 ohm, then 90 ohms per phase would be required to operate at 0.1 per unit speed.

Therefore, Figure 12 suggests that there are practical limits to the amount of speed reduction which can be provided with centrifugal fan, pump, or compressor loads. These limits are derived from various factors which depend on the specific application, and a comprehensive discussion on this subject is beyond the scope of this article. However, these factors are listed:

1. Control sensitivity.
2. System stability.
3. Rating of the motor.
4. Maximum practical stroke of the electrodes.
5. The load characteristic.

Where $T=1.0N^2$, the power dissipated in the rotor circuit resistance may be derived as follows:

$$P_R=I^2R$$

Assuming the motor operates at a rated voltage, $T=I=1.0N^2$ and using equation 3, we have,

$$P_R=SN^2, \text{ where } S=1-N \qquad (4)$$

This relationship is plotted in Figure 13 and represents the power that has to be absorbed by the liquid rheostat at any

Figure 13. Rotor power dissipation versus speed for a load torque $T=1.0N^2$

steady-state operating speed. Obviously, this power dissipation affects the over-all efficiency of the motor drive, but its effect cannot be considered unfavorable or prohibitive. As a matter of fact, the curve shown in Figure 13 is inherent also for magnetic and hydraulic couplings, a factor which makes all of these methods of speed adjustment comparable in over-all efficiency.

Constant Torque Loads. Another common type of load characteristic is "the constant torque load." Figure 14 shows, for a constant torque load $T=1.0$ that it is possible to provide speed adjustment over a wide range with relatively low values of external rotor circuit resistance. However, this is achieved at the expense of high power dissipation in the rotor circuit. For example, to obtain 0.5 speed reduction, Figure 14 indicates that $R=0.5$. From Figure 15, the corresponding value of power dissipation in the rotor circuit is $P_R=0.5$ of rated motor horsepower. The significance of this example can be expressed as follows:

1. The over-all efficiency of the motor drive is low at low operating speeds.
2. The dotted curve shown in Figure 15 is taken from Figure 13 (for a load $T=1.0N^2$) and is drawn for comparative purposes.

It illustrates that for the same speed reduction, the liquid rheostat installation for a constant torque load must dissipate more power and hence it is a more expensive installation.

Because of the above economic limitations, the operating speed range is usually small for a constant torque load. In such applications, the liquid rheostat is used more as a load-regulating element. This type of application will be discussed later.

Control Systems

Manual Control System. One of the simpler methods of speed adjustment is illustrated in Figure 16. The electrodes are positioned to obtain any desired operating speed by manual control for the pilot motor on the rheostat. Once positioned, the electrodes remain stationary.

This scheme inherently provides smooth or "stepless" speed adjustment. The accuracy with which speed is maintained at fixed electrode spacing depends on constancy of the load torque and electrolyte temperature.

The temperature regulating valve which is usually provided in the electrolyte circulating system serves to maintain the electrolyte temperature within reasonable limits. However, the thermal storage in the volume of electrolyte and the fixed

Figure 14. Resistance versus speed for a load torque $T=1.0$

pumping capacity result in a time delay for the electrolyte temperature to respond and reach a steady operating value. This thermal lag is reflected as a drift in speed after each change in speed setting and particularly after acceleration from rest.

To appraise the effect of electrolyte temperature fluctuations, consider a 20 per cent increase in external rotor circuit resistance at 50 per cent speed and again at 90 per cent speed, for a motor driving a load where $T=1.0N^2$. Refer to Figure 12.

1. At 50 per cent speed, $R=2.0$ initially and it changes to $R=1.2\times2.0=2.4$. From Figure 12

$$2.4=\frac{(1-N)}{N^2} \text{ or } N=0.47$$

The speed changes approximately 6 per cent for a 20 per cent change in rotor circuit resistance.

2. At 90 per cent speed, $R=0.124$ initially and it changes to $R=1.2\times0.124=0.15$.

$$0.15=\frac{(1-N)}{N^2} \text{ or } N=0.88$$

The speed changes approximately 2.3 per cent for a 20 per cent change in rotor circuit resistance.

Figure 15. Rotor power dissipation versus speed for a load torque $T=1.0$

Figure 16. One line diagram of a manual control system

For specific applications, the performance of the manual control system can be appraised in somewhat the manner described above. The results may show that this type of system is satisfactory and meets the particular operating requirements.

Speed Regulating Control System. A more refined scheme of speed adjustment is illustrated in Figure 17. The pilot motor on the liquid rheostat is energized by an amplidyne. The amplidyne, in turn, responds from the control unit, which compares the speed adjustment setting of the speed-adjusting rheostat with the motor speed, as detected by the tachometer generator. Any divergence from the desired setting results in smooth, automatic positioning of the electrodes to correct and maintain the speed within precise limits. Current limit action is usually provided to prevent the motor current from exceeding a preset value during acceleration.

The speed regulating control system has several features and advantages as follows:

1. It is a variable-response system, that is, when the motor speed diverges from the desired setting, the magnitude of the correction signal is directly proportional to the value of the divergence. Thus, for a large divergence in speed, the electrodes move rapidly to correct the speed. Conversely, for a small divergence, the electrodes move slowly to correct speed. From an operating standpoint, the variable-response system results in fast response with stable operation.

2. It provides current-limit acceleration. Figure 18 illustrates a control motor speed-torque curve *A-B-C-D-E* for acceleration from standstill to the preset value, $N=0.9$ speed. Figure 18 assumes a load where $T=1.0\ N^2$ and a maximum liquid resistance per phase, $R=2.0$, which gives a stalled motor torque $T=0.5$ at point *A*. On energizing the motor, the current-limit control positions the electrodes to increase the motor current smoothly along curve *A-B*. From point *B* to point *C* speed control automatically becomes effective and stabilizes the speed at point *D*, the preselected value.

3. It virtually eliminates fluctuations in speed otherwise caused by electrolyte temperature drifts. This means that the speed at any setting is reached quickly and is thereafter maintained within close limits. Envelope *G-H-K-P-G* of Figure 18 can be designated as the control range envelope. For the speed regulating control system under consideration, the control range envelope has particular significance. It means that for any normal speed setting, the load can change between the limits established by the envelope, and the steady-state speed setting will be maintained closely and without overloading the system.

4. Referring again to Figure 18, the envelope *G-H-K-P-G* is established by the following factors:

a. The Heat Exchanger Capacity. Segment *G-H* gives values of torque versus speed for constant power dissipation in the rotor circuit. The heat exchanger capacity is arbitrarily assumed to be $Pr=0.148$ or 14.8 per cent of rated horsepower (refer to Figure 13).

b. The continuous rating of the motor segment *H-K* is for rated motor torque.

c. The Internal Rotor Circuit Resistance and the Minimum Resistance of the Liquid Rheostat (electrodes down). These resistances determine the slope of segment *K-P* by the relationship: the minimum motor slip (at point *k*) equals the sum of the per unit values of the internal rotor resistance of the motor and the minimum resistance in the liquid rheostat.

d. The Maximum Resistance of the Liquid Rheostat (electrodes up). Segment *P-G* arbitrarily is for $R=2.0$.

For example, in Figure 18 the speed setting assumed gives the controlled motor torque characteristic *C-D-E*, the slope of which is established by the sensitivity of the regulating control, and, in an ideal sense, can be assumed to be almost vertical. The load torque can change between a value $T=1.0$ (at the intersection of curves *C-D-E* and *H-K*), and the value of torque corresponding to point *E*. The final steady-state operating speed will lie on curve *C-D-E*. The foregoing can be extended for any other speed setting within the control range envelope.

It is necessary to qualify the nature of the load changes considered in the preceding discussion. Although the steady-state operating speed reached after a load change will lie on the controlled motor characteristic such as *C-D-E* of Figure 18, it is apparent that the speed will change during transient conditions, that is, during the time the load is changing.

Changes in load may be classified as:

(1) Gradual
(2) Rapid
(3) Impact

A gradual load change is one which occurs at a rate which is within the response of the control system, that is, at a rate which the control system can follow with permissible transient speed variations. The rapid load change or the impact load change impose limitations which require special measures. The load regulating control system which will now be discussed can be adapted for certain applications which involve rapid or impact load changes.

Load Regulating Control System. This scheme is illustrated in Figure 19 and is usually applied to maintain constant input to the motor or to prevent the load on the motor from exceeding a selected value.

The torque motor on the liquid rheostat is energized by an amplidyne. The amplidyne in turn, responds from the control unit, which compares the load adjustment setting of the load control rheostat with the primary current. Variations from the desired setting cause automatic positioning of the electrodes to vary the speed to maintain essentially constant input to the motor. The electrode operating mechanism is designed to make possible very rapid movement of the electrodes.

The load regulating control system can be adapted as follows:

1. To regulate and maintain operation at essentially constant torque.

2. To operate as a current-limiting or "cushioning" control under rapid or impact load changes of short duration. The drive usually includes a heavy flywheel, and the drive motor is intended to operate at essentially constant speed. For normal loads

Figure 17 (left). One line diagram of a speed regulating control system

Figure 18. A controlled motor characteristic and the control range envelope

the electrodes are in the "down" or maximum speed position. When a heavy impact load occurs, the sudden increase in motor current causes the electrodes to operate very quickly and insert resistance in the rotor circuit. This tends to decrease the motor speed. However, the flywheel minimizes the speed change by giving up some of its kinetic energy. The net result is that the power input to the motor is held within the load setting. When the impact load disappears, the electrodes automatically return to the maximum speed position.

Figure 19. One line diagram of a load regulating system

Other Control Systems

The liquid rheostat, as a system element, in conjunction with the proper control, can be applied in various other ways. In some cases, a pneumatic or hydraulic cylinder can be used to operate the electrode mechanism directly. The cylinder, in turn, is positioned from a regulating control sensitive to any desired quantity such as:

1. Temperature.
2. Flow.
3. Level.
4. Pressure.

The liquid rheostat is particularly suited for control of larger motors, where other types of control cannot be used because of rating limitations. For the smaller motors the liquid rheostat is on a more competitive basis with other types of control. However, on these smaller sizes, an integral assembly comprising liquid rheostat, heat exchanger, circulating pump, and other associated devices, together with the features of stepless and precise control, will doubtless lead to wider use in the future of the liquid rheostat for control of smaller motors.

Discussion

W. Schaelchlin (Westinghouse Electric Corporation, Buffalo, N. Y.): The paper presented by McFarland and Alvarez gives a very good conception of the performance and application of the liquid rheostat. They emphasize its inherent simplicity of design and large capacity to store and dissipate energy which offer a decided advantage over other methods of speed control.

In designing its new line of liquid rheostats, the Westinghouse Electric Corporation has endeavored to "streamline" their appearance and to provide a completely closed system both for the electrolyte and for the cooling water. Another desirable improvement, particularly for high voltage applications, is obtained in the special arrangement of the stationary electrodes. With this design there is no danger whatsoever of a possible insulation failure, because each phase tank is made of insulation so that a maximum insulation is obtained when the voltage between the electrodes is highest.

Figure 1 of the discussion illustrates a cubicle for a complete secondary control with liquid rheostat built to control the speed of a 750 horsepower induced draft fan motor. It is completely enclosed and its appearance can be made to match that of the primary control having standard cubicle dimensions. A rear view is shown in Figure 2 of the discussion which illustrates the arrangement of the three rheostat tanks permitting a large speed reduction. The operating mechanism as well as the usual

Figure 2 (right). Rear view of secondary control cubicle showing liquid rheostat

Figure 3 (left). Front view of secondary control cubicle showing operating mechanism and sump tank with pump

Figure 4 (right). Liquid rheostat for 10,000 horsepower wind tunnel motor

Figure 5 (below). Stationary electrode arrangement for a 25,000 horsepower liquid rheostat

control gear are mounted in the front of the cabinet which permits ready accessibility of all parts, as shown in Figure 3 of the discussion. Attention is also called to the sump tank and the electrolyte circulating pump located at the lower right side. This pump is completely submerged in the electrolyte so that any possible leaking of the glands is of no consequence and very little maintenance is therefore required to maintain a clean looking control equipment.

Figure 4 of the discussion shows a liquid rheostat for a 10,000 horsepower wind tunnel motor. The upper part consists of the cubicle with the necessary control mechanism as well as the headers for both the cooling water and the electrolyte. The cubicle itself is mounted level with the floor for easy accessibility while the three insulated tanks extend below the structure into the basement.

Considerable attention has been given to the mounting of the stationary electrodes clamped to the lower end of the insulated rheostat tank. By using a bevelled ring and groove arrangement, as illustrated in Figure 5 of the discussion, it was possible to obtain a simple and reliable joint that permits ready removal of the electrode for inspection purposes. It is interesting to note that Figure 5 illustrates the stationary electrode for a 25,000 horsepower liquid rheostat with an active electrode diameter of approximately 30 inches.

G. L McFarland: In the second paragraph of Schaelchlin's discussion, the Westinghouse liquid rheostat is discussed in which the statement is made concerning "a completely closed system for both the electrolyte and for the cooling water." Apparently, from Figure 2 in the discussion, the movable electrode is suspended on a flexible cable from the pulley wheels located above each cell. The writer assumes that there is a nominal clearance between the flexible cable and the cover of the cell even though it is not shown clearly in the photograph.

In order for the movable electrode to drop freely when the pulley shaft is rotated, close clearances cannot be used between the cover and the cable.

The fact, however, that the entire liquid rheostat is enclosed in a cubicle plus the fact that the cover on each cell must be fairly close-fitting should provide complete protection against dust and dirt entering the electrolyte system. This is what is meant by "a completely closed system."

In a new General Electric design of a liquid rheostat, we are enclosing the entire electrolyte system by other means which fit into our particular design. Evaporation losses in both designs are held to a minimum by such enclosures.

The "Director" for Automatic Telephone Switching Systems

ARTHUR BESSEY SMITH
FELLOW AIEE

THE TELEGRAPH was invented in 1837 by Morse. In 1876 came the invention of the telephone by Bell. By this time the switching of telegraph lines had developed into a definite system, characterized by plugs and jacks for easy connection and disconnection. Each connection lasted for a relatively long time, hours often running into days.

The first telephone switchboards were very much like the telegraph switchboards. But the telephone naturally required many connections and disconnections per hour, each connection lasting only a few minutes. This led to making the plugs and jacks smaller and more easy to handle.

It is a remarkable fact that very soon after Bell's invention the first attempts were made to do the telephone switching automatically ("to do by a machine that which formerly was done by hand"). And about 1891 the work of Almon B. Strowger got started, which developed into that of the Automatic Electric Company. It was the adoption of that system of automatic switching for the London, England, telephone exchange that led to the invention and development of the "Director," which is the subject of this paper.

The Director is a telephone switching device which stores the dialed call number and then sends out decimal impulses which guide the connection to the desired telephone office and to the called line.

When electric light and power came to London, the authorities ruled that all wires must be laid underground. The first telephone system in London, like others of that era, was entirely manual, and also was forced to put its wires underground.

In addition to slowing the growth of telephone use, this tended to fix the routes of telephone cables and to make it difficult to open new routes between offices as new offices were opened. To use tandem trunking was cheaper than to install direct trunks between all offices.

Direct trunks with straightforward dialing has much to commend it. There being no Director, there is no storage of impulses and no loss of time due to that. The subscriber pulls the call number, and when the dial gets home from the last digit, the connector has arrived at the called line. There remains only the short time to test the line, and if free, to start the ringing, which the subscriber can hear. Also, there is the psychological aspect—he has been usefully employed during the time and his wait is short.

It is tandem trunking which makes the Director necessary, as also the great desirability to be able to call a certain telephone by the same call number no matter where the calling subscriber may be located—the universal numbering plan.

Tandem trunking and the Director have been very much considered in America also. In fact, the director was installed in Havana, Cuba, and in a private automatic exchange (PAX) in Kansas City, Mo., before the London system was put into service.

There are also cases in small communities where the Director will serve. If it is desired to permit subscribers to dial over a county, without any intervening operators, many of the paths will pass through switching points, and others may use direct trunks.

The present day prospect of nationwide toll dialing in the United States of America, for which the Director is ideally suited, is one of the chief reasons for calling the Director to your attention.

Universal Numbering

Consider two small towns, not too far apart, each served by a 100-line automatic switchboard, with only 80 lines in use. Figure 1 illustrates the condition, omitting all the dotted lines. All calls in each town are made with two digits, and only connectors are needed.

If someone gets the idea of permitting the subscribers freely to dial each other between the two switchboards, the dotted lines and switches may be added. There may be incoming connectors C' whose banks are multipled onto the banks of the local connectors C. Suppose that the top level of each local connector is set aside for trunking to the other board. Thus, any subscriber in M will dial two digits to get others in his same town, but must prefix *0* to get any telephone in J. Likewise, any J subscriber must prefix *0* to get any telephone in M.

The following situation arises. To call telephone *25* in the M region, dialing from any other telephone on the M switchboard, requires the dialing of only *2* and *5*. But to dial the same telephone from any telephone connected to the J switchboard requires the user to dial *025*. This is *not* universal.

Figure 1. Two exchanges, not universal numbering

Paper 48-99, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 28, 1947; made available for printing December 29, 1947.

Arthur Bessey Smith is vice-president, Automatic Electric Laboratories, Inc., Chicago, Ill.

Thanks are hereby expressed to John E. Ostline (F'46) and to other members of the staff of the Automatic Electric Company for the facts and suggestions on which this paper is based.

Figure 2. Two exchanges, universal numbering

Now consider Figure 2. Each of the two switchboards now has selectors *S* as well as connectors *C*. Every telephone has a 3-digit call number. As sketched, the telephones in *M* are in the 300 group and those in *J* are in the 400 group. The former telephone *25* in *M* now can be called by dialing *325* in either town. It is thus with all the telephones. This is *universal numbering*.

Tandem Trunking

Let the four offices, *E*, *J*, *K*, *M*, Figure 3, of a multioffice exchange be interconnected as usual by direct trunks. To serve a new region, office *X* is built. By reason of the local geography it would be too expensive to install direct trunk groups between the new office *X* and each of the older offices. Hence it is decided to have all calls from and to the *X* office switched at *J*. Any call from *E* or *K* or *M* would be dialed to *J*, where an additional digit would reveal that the call goes to *X* instead of to telephones connected to *J*. This is tandem trunking. If there is no Director, or its equivalent, this can not have universal numbering.

Also notice this, if a subscriber in *J* calls one in *X*, he will dial perhaps four digits. But if a subscriber in *E*, *K*, or *M* desires to call a telephone in *X*, he must first dial a digit to get to *J*, then followed by the call number for the *X* telephone. Thus the number actually dialed will depend on where the caller is located, and it is not universal numbering.

But let us place in each of the five offices a number of switching devices known as "Directors." Each of these has been so designed that it can direct or guide a call to the desired distant office no matter what route it must take. Each of these Directors is accessible to all calls coming from subscribers in that office. It is convenient to arrange it so that when a subscriber initiates a call, he will as usual get a first selector, and an idle Director will at once be associated with that first selector. The entire call number (for example, *6258*) will be dialed into the Director, and registered there. The Director has been endowed with enough electrical and mechanical judgment to know, from the first digit, *6*, that it must first send the digit *3* into the first selector to extend the line to the *J* office, to follow this by digit *6* into an incoming selector in the *J* office to cause it to rise to the group of trunks leading to the *X* office. After this, the Director will send the rest of the call number "*258*", which operates switches in the *X* office to connect the desired line. The other offices are likewise equipped with Directors having equal abilities, so that no matter where you are in the city, you can dial your friend in office *X* by the one call number, and you will get the right telephone. This is how the Director permits *universal numbering*.

This paper describes the structure of the Director, how it works, and the variety of things which it can do. It does not attempt to describe exhaustively the basic principles of tandem interoffice trunking, nor the most economical use of the equipment. But it does show the flexibility of the Director and how it can be made to serve the exchange designer and through him the public.

The London Automatic Telephone Exchange

On about the first of January 1922 the Automatic Electric Company was asked to develop an apparatus which would enable the London exchange to convert to automatic switching without installing direct trunks between all offices. Regular Strowger type numerical switches would switch the connections to their destinations.

M. L. Nelson and R. G. Richardson worked out the general plan and the circuit details and by January 6 they completed the first drawing showing practically all the details of a working Director. Though there have been numerous changes, yet many of the features of that first layout were fundamental and have remained for that reason.

In the year 1924 a Director system was built and installed in the Havana, Cuba, exchange.

In the spring of 1923 John E. Ostline went to England in charge of the further development of the circuits, and out of his work have come many improvements, some of great economic value. In 1924 they began to build the apparatus for London and in 1927 the first of it was cut into service. Since then the progress of development has been fairly steady.

Figure 3. Tandem trunkin

First Aspects of the London Director

The situation may be illustrated by the following things which presented themselves to the designer:

1. The universal call number, such as *DAVis-8019*.
2. Tandem trunking.
3. Straight Strowger dialing of impulses, clear through to the distant office.
4. Trunk to manual offices with call indicators for the operators, at least during the transition period.

The use of the name of an office (such as Davis, Monroe, Humboldt) is a device to aid the memory of the user. It makes it more easy to remember the number from seeing it in the directory to spelling it out on the dial. The arrangement of the letters of the alphabet on the dial is well known. The first letters of the office name, which are to be dialed, are known as the office code, such as *DAV*. Dialing it results in a "decimal equivalent" such as *328*.

The coming of the Director has required the use of certain words and expressions, each to have a definite and clear meaning, so as to avoid confusion. I will illustrate by the call number *DAVis-8019*.

1. *DAV* is the office code.
2. *328* is the decimal equivalent of the office code.
3. *MNOP* or other digits form the directive. By the action of the director they are derived from the office code and they guide the call to the distant office. The number of digits in a directive depends on the route.

Figure 4. London plan, general, call registry

Figure 5. Ratchet magnet, direct drive

4. Directive selectors are those which are in the train leading to the distant office. Each is operated by one digit of the directive.

5. *8019* is the terminal number. As usual, the digits are called "thousands", "hundreds", "tens", and "units."

6. The thousands selector and the hundreds selector are in the distant office and handle the digits indicated by their names.

7. The connector connects to the called terminal.

The London situation led to the following first approach:

1. Carry the terminal number through unchanged (such as *8019*).

2. Transform the decimal equivalent (such as *328*) into a directive (one to six digits) to steer the call to the distant office.

3. The Director was required to store all digits dialed by the subscriber, transform the decimal equivalent of the office code into a directive, send it, and repeat the terminal number unchanged.

The Director was composed of the following subordinate devices.

1. The inward path, which guides the dialed impulses into the director.
2. The *ABC* register, on which the three decimal equivalent digits are stored.

3. The terminal number register, on which the four digits of the terminal number were stored. There was no provision for party lines.

4. A register sequence switch to guide the incoming digits, each to its appropriate register.

5. A translator, to change the *ABC* code (its decimal equivalent) into from one to six digits, called the directive.

6. An outward path from the Director to the first directive selector (in this office), from which place the path will be extended to the distant office and the called line.

7. An impulse generator, a device which generates correct impulses to be sent over the outward path.

Having seen the general plan of the Director, we are rightly interested in the various circuits used to accomplish the results. It is not practical to discuss the entire circuit assembly just now, for it is too complicated. But there are certain key circuit devices about which you are justly curious, and these we will examine now.

Many circuit details are involved, too many to cover in one paper. For some details I will use "outline symbols", combined to show the general relationships and then describe several circuit devices and their combinations to reveal the structure and action. To save space, some symbols will be used without explanation.

Call Registry

The registry of the call number is outlined in Figure 4. The telephone line comes through such nonnumerical switches (*Non*) as are used. These may be line switches or line finder switches. The trunk passes to a group of trunk relays, where two chief paths run to the banks of a group of line finders, presided over by a call distributor. The latter sends one of the line finders to seek the incoming call. Thus it is connected to an idle Director. Only the registry parts are here indicated by single line diagrams and symbols.

The incoming path from the subscriber passes through a slow relay (slow series) to the wiper of the register sequence switch. From the bank of this switch lead wires to the *ABC* code register and to the four digit registers for the terminal number (*Th*, *H*, *T*, and *U*).

The *A* digit (for example, $D=3$) operates the motor magnet *MM* of the code *A* register to contact 3 on the bank. At the same time, the slow relay has energized the motor magnet of the sequence switch, so that at the end of the impulses the slow relay falls back and de-energizes the motor magnet, whereupon the wiper moves to the next bank contact. The next two digits from the telephone operate first the vertical magnet *VM* and then the rotary magnet *RM* of the code *BC* register. This is a 2-motion Strowger switch. The second digit (for example, $A=2$) lifts the wipers to the second level, and the third digit (for example, $V=8$) rotates the same wipers to the eighth set of contacts on that level. In the meantime, the slow series relay of the sequence switch has advanced the wiper to contact 4.

It is now clear how the remaining digits for the terminal number are directed successively to the motor magnets for the thousands, hundreds, tens, and units registers.

Thus by the positions of the wipers of the *BC* register we have a recording of the office code (its decimal equivalent) and by the positions of the four wipers of the terminal register an indication of the terminal number as it appears in the telephone directory.

Magnet Ratchets

Two ratchet devices are used, each with its own properties and performances.

Figure 6. Minor switch

Figure 7. Strowger switch

They enable circuit designers to obtain valuable results.

Figure 5 illustrates the direct magnet drive, used in the minor switch (Figure 6) and in the vertical and rotary movements of the Strowger switch, Figure 7. When the magnet, Figure 5, is energized, the wipers move to the next contact. When the magnet releases, there is no circuit change—the ratchet is made ready for the next step. Such a ratchet action moves against a restoring force, gravity in the vertical movement of the Strowger switch and a spring in the rotary motion, as also in the minor switch. In each case there is a detent, holding the ratchet teeth from moving backward. Return to normal is by a release magnet which pulls out the detent. The minor switch is used for the register of the digits of the terminal number and the Strowger switch for the *BC* code register.

Figure 8 illustrates the spring drive, used in the rotary line switch (Figure 9). When the magnet (Figure 8) is energized, the pawl engages the next tooth but the wipers do not move. When the magnet releases, the spring drives the wipers to the next contact. This kind of switch is returned to normal by causing the motor magnet to buzz like a doorbell, so driving the wipers around the circle to the home position. This is used in the register sequence switch and elsewhere.

The Impulse Sender

The basic principle by means of which properly registered digits can be sent over the outgoing path or loop to the selectors is illustrated by Figure 10. Suppose that each of the three registers, *H*, *T*, and *U*, can be set by hand to any desired digits. I will assume *3-2-5*. Let the sequence switch *Seq.* be arranged to be moved by hand from its home contact to each of its bank contacts in sequence.

The impulse sender itself, as here abstracted, consists of a rotary switch with wipers *W* and *W'*, stepped by a motor magnet, *MM*. This is of the spring-drive type, described previously. A stop relay is connected to the wiper *W*.

Figure 8. Ratchet magnet, spring drive

In the upper right corner of the figure is the loop leading to the first selector, and through it to other selectors in the train. Two relays close it normally, by their back contacts, relay *D*, wired to wiper *W'*, and the interrupter relay *IR*, controlled by the interrupter itself. The interrupter *I* is running steadily at the rate of ten impulses per second, and the ratio of break to entire period is correct to operate the numerical switches in the train.

Two functions are essential, to start interruptions of the loop with a full-time break (not part of one) and to stop the sending when there have been sent the number of breaks indicated by the setting of any one of the registers.

We have by hand set wiper *H* to *3*, *T* to *2*, and *U* to *5*. Then we set the sequence switch onto the *H* contact of its bank. Then we press the start key and hold it down.

If the time of pressing happens to be too late in an impulse of the interrupter, relay *IR* will fail to pull up, or make a feeble or partial response. This does no harm. But the next time *I* closes, it will operate *IR* for the full time. This energizes the motor magnet, *MM*, which pulls its armature to cause its pawl to engage a tooth. When *IR* falls back, *MM* will de-energize and drive the wipers *W* and *W'* to the next contacts. Here *W'* operates relay *D*, which pulls up and remains operated to the end of this digit, opening its contact and thereby putting the loop entirely into the control of the *IR* relay.

The next impulse from *I* operates *IR* as before, which causes *MM* to advance the wipers to contact 1. The arrival of wiper *W* at contact 1 permits the stop relay to find out if it is grounded. It is not, so two more impulses bring the wipers to contact 3, which is grounded by our setting of the *H* register and the position of the sequence switch. At once the stop relay pulls up, breaks the start wire, and ends the sending of three impulses over the loop. There were only three impulses and all of them were perfect.

In addition to stopping the impulses, the stop relay locks itself to ground on a contact of relay *D*, also connects the self-interrupter contact of the motor magnet to wiper *W'*. At once the motor magnet starts to vibrate and thus drives the wipers *W* and *W'* around the circle to the home position. Here the ground is removed from *MM* and relay *D*, the latter releases the stop relay, and ("start" being opened) the sender is ready for the next digit. Now we may move the sequence switch to the *T* contact, close the start key, and the sender will do the same process all over again, this time sending two good impulses. Moving the sequence switch to *U* will cause the same to be done for the units digit.

Translation—Decimal Equivalent Into Directive

Consider the *ABC* code registers which were discussed in Figure 4. The *A* register is a simple rotary switch of the "minor switch" type, and is set by the decimal equivalent of the first letter. This connected the impulse circuit to the vertical magnet, then to the rotary magnet of the selected *BC* register. This Strowger switch registered the *B* and *C* digits by its "up and around" movement of four wipers.

Now consider Figure 11 which illustrates the translation of the decimal equivalent of the office code.

Each Director has one code *A* register, to whose bank are wired eight code *BC* registers. I have illustrated this by only three of them. From the *A* register bank contacts the wires run to the magnets of the *BC* switches. The wipers of all the *BC* switches are multipled, each to each, and run to the bank of the sender sequence switch. The banks of the *BC* switches are wired separately to one side of an intermediate distributing frame, *IDF*. The other side of that *IDF* is wired to the bank of the sender switch, where the sending of impulses over the loop will be governed. In this simplified illustration I have shown only two wipers for each *BC* switch. There were six wipers on each switch as planned for London.

Figure 9. Rotary switch

Figure 10 (left). Register to sender relationship

Figure 11. Translation of decimal equivalent into directive

Let us assume the following relations.

Decimal Equivalent	Directive
243	32
324	41
433	53

On the *IDF*, jumpers would be run as shown. For example, the number 2 *BC* switch bank contact 43 would have its bottom contact of the pair wired to *3* on the right side and its upper mate wired to *2* on the right side. The other jumperings are self-evident. In practice all the bank contacts of the eight *BC* switches are similarly jumpered, according to the pathways which each interoffice call must take.

If the call which we are considering be *243*, the *A* switch will be on its number 2 bank contact, and the number 2 *BC* switch will have its wipers resting on its fourth level, and the third pair of contacts. Now when ready to translate and send, the sender sequence switch will move one step, thus grounding all the lower wipers of the *BC* switches. Only the lower wiper of the number 2 switch is connected—the others are normal and open. This move of the sequence switch starts the sender which performs as described in connection with Figure 10 and cuts off when three impulses have been sent. Then the sequence switch, Figure 11, will move to its next contact, switching the ground to the upper wiper, and start the sender on its next round.

The performance is similar for any other decimal equivalent.

In the actual case of four wipers for each *BC* switch, the sender can send four digits in the directive. The maximum number of digits in the directive fixes the number of wipers needed.

It is the ability to move to a desired position any reasonable number of wipers that gives to the Director the possibility of sending out almost any kind of directive, one digit for each wiper which has been set. If the office code has only one digit, and the directive might have as many as four digits, a minor switch (rotary motion only) with four wipers can do it. If the office code has two digits, a Strowger switch (two motions, up and around) will serve, with as many wipers as the largest number of digits in the directive. For the usual 3-digit office code, a minor switch for the *A* digit and a Strowger switch for the *B* and *C* digits will serve, the Strowger switch having as many wipers as the largest number of digits in the directive.

Having seen how the call number is registered and how several functions work, let us see how they are controlled and co-ordinated in sending out the directive. Assume a call number *324-5342*. According to Figure 4 the first digit has rotated the *A* register three steps, the next two digits have lifted the wipers of the *BC* register two steps and rotated them to the number 4 set of bank contacts. Further, the dialing of the terminal number has set the wipers at contacts 5-3-4-2, respectively, as shown in Figure 12.

Assume that to reach the distant office the Director must send the digits *4* and *1*. The bank contacts of the *BC* switch had been cross-connected to the decimal terminals *4* and *1*, on the *IDF* (at the time installation).

Thus we have in the register bank multiple a complete representation of the digits which are to be sent, and the bank of the sender switch carries this bank multiple with the wires in numerical order. The sender is ready to obey the indications thus presented.

There is one exception, the "skip digits." Because the decimal equivalent (*324*) of the office code requires only a 2-digit directive, the upper pair of wipers on the *BC* switch are not needed. They are cross connected on the *IDF* to two contacts on the bank of the *R* wiper of the sender sequence switch. As described later, this causes the sequence switch to pass by those wipers quickly without waiting for any impulse sending.

Sending the Impulses

Just as was illustrated by Figure 10, we are to govern the number of impulses sent in each digit by means of a grounded contact on the bank of a register. Figure 12 shows all eight wipers, four in the *BC* register and four registers for the line number. The ground is to be placed on those wipers in succession, by means of wiper *S* of the sender sequence switch. Each time that the sequence switch advances and thus grounds a new wiper, it starts the sender on a round of exploration by means of the "start sender" wire. When the sender switch has made a cycle and returned to the home contact, it advances the sequence switch by means of the "sequence" wire.

To avoid too much complexity I have omitted from Figure 12 all the details which could be spared, trying to leave only those which will make clear how translation of the office code and the sending of impulse digits are done.

The *BC* register is controlled by the calling subscriber through a line relay *LR* in the trunk repeater. Assume that the wipers of the *BC* switch have been lifted by the second digit. As the line relay repeats the impulses sent by the subscriber, the rotary magnet *RM* steps the wipers around. At the same time the series relay *Se* pulls up and remains operated. It operates relay *F*, which locks to a ground in the trunk repeater. When the third digit ends, *Se* releases and grounds the start wire for the sequence switch. Wiper *R* connects to the self-vibrating contact of the motor magnet *MM-1*, which promptly advances the sequence switch wipers one step. This put the *S* ground on wiper number 1 of the *BC* switch, and at wiper *SW* the same start wire ground is applied to the impulse relay *IR* of the sender. As was described for Figure 10 the interrupter *I* acting through *IR* (Figure 12) steps the sender switch around to contact 4, having thus sent four impulses over the loop to the first selector.

At the beginning of impulsing, relay *D* pulled up to clear the loop for *IR*, and also pulled up *MM-1* of the sequence switch,

holding it operated as long as the sender is operating.

Having sent the four impulses, the sender switch rotates around to its home position, both bank contacts of which are open. Relay *D* releases and thus releases the motor magnet *MM-1* of the sequence switch, and advances its wipers to the next set of contacts. Here the *S* ground is placed on wiper number 2 of the *BC* switch and the sender started again, this time sending only one impulse.

Wiper *SW* has been the means for starting the sender. Its next two contacts are open, but the corresponding contacts of wiper *R* have "skip" wires, leading to the bank contacts of the *BC* switch which are occupied by wipers 3 and 4. Hence the ground applied by wiper *S* operates to cause the motor magnet *MM-1* to rotate wiper *S* (and all the others) quickly past wipers 3 and 4 without sending any impulses to the loop.

Placing the start wire of the sequence switch into the control of the *BC* switch is to insure that the subscriber has dialed all of the office code. The directive can not be specified until all the code digits are registered. But after that time, the directive can be sent, without waiting for the registry of the line number.

But the terminal number, though sent out as received, can not be sent until it is received. For this reason, the starting of the sender is now changed to off normal springs *ONS* on the line registers. When any one of them is dialed away from its normal position, the *ONS* grounds a wire leading to the bank of the wiper *SW*. Thus the sender can send each digit in succession as fast as it is registered.

Holding Circuits and Release

During the registering of the call number and the sending of the directive, ten switches are held, either passively or actively. The holding circuits for these are shown in Figure 13. In the upper left hand corner are the line relay *LR* and the associated slow relay *6*, both of which are located in the trunk between the incoming line and the first selector. The slow relay holds the trunk from releasing, even while *LR* is impulsing into the director.

The main holding circuit passes from the slow relay *6* to the finder switch, thence through the register sequence switch, the code *A* register, ending in the *BC* register switch. In the finder switch, relay *9* is holding the connection through its wipers, in the *BC* switch relay *11* is withholding ground from the release magnet. The *10* relay in the register sequence switch is controlling the release of six switches, the sequence switch, the *A* register, and the four line registers, *Th*, *H*, *T*, and *U*. In addition, it is in a position to ground the *W-3* bank of the sender sequence switch to chase it home.

In Figure 13 we note also the means to switch the subscriber line through to the selectors and thus to the called telephone. Relay *7* is the through-switching relay in the trunk circuit. It is connected through the finder switch to the sender and the sender sequence switch as shown.

As soon as the sender reaches home from sending the last digit of the call number, relay *D* of the sender (Figure 12) falls back quickly, but the stop relay hangs on for a moment. The release of *D* permits the sender sequence motor magnet *MM-1* to release, which quickly snaps the wipers to their contacts *S*. This (Figure 13) completes the path between the ground at the stop relay through bank and wiper *W-2*, again through the sender circuit, the finder switch, to the switching relay 7 in the trunk circuit. Then the stop relay of the sender falls back.

The switching through of the telephone to the train of switches has cut off line relay *LR* of the trunk, so that it and the slow relay *6* release. This takes the control trunk ground from the entire system of five relays, affecting seven release magnets. Relay *9* severs the finder switch connection, relay *11* operates the release magnet for the *BC* switch, relay *10* of the register sequence switch operates the release magnet of the *A* register, and all four of the release magnets of the line registers. In each such case, the release magnet is cut off by an off normal spring, which breaks its circuit when the switch reaches normal.

Another ground contact on relay 10 grounds the bank of wiper *W-3* of the sender sequence switch, whereupon the motor magnet *MM-1* interrupts its own circuit and steps all its wipers around to the home position.

The Director is now ready to care for another call.

In spite of the many words which I have used in this explanation, the entire release time is very short, usually not more than one-half to one second.

The Later Director

From time to time, improvements have been made in the Director. Out of them have come some very interesting structures of circuits resulting in economy of apparatus and greater flexibility. In the arrangement which I will now describe, part of the apparatus is common to a number of directors, being released as soon as its work has been done.

In Figure 14 the telephone *Telo.* is connected through nonnumerical switches *Non.* to an idle first selector. Out of the associated relays come several wires to a director hunter by means of which an idle director is found and seized.

At the right are the registers in which are to be stored the information which shall guide the sender in sending groups of impulses to the train of numerical switches leading to the distant office and subscriber line.

The dialed impulses pass through a relay *A1*, which repeats them to the magnets of the registers. There is a series slow relay which pulls up on the first impulse, remains energized, and after

Figure 12. Registers and sender details assembled

Figure 13 (left). Release circuits

Figure 15. Translation and storage, general principles

the digit is registered, releases and causes the register sequence switch *Reg. Seq.* to advance one step. Three office code digits are followed by the line number, which the register sequence switch delivers to the motor magnets of the four line registers in succession.

The wiper and bank marked *Reg. Seq.* have wiper *U* on the same shaft. During the latter part of its rotation, this switch acts as the units register of the line number.

The storage relays with their sequence switch will handle the directive and later will feed it into the decimal multiple.

Figure 14. Improved Director, general plan

Below the dashed line are four sets of apparatus which are common to as large a number of directors as the traffic needs. First is the *A* register hunter which finds and seizes an idle *A* register. This is a Strowger switch, whose vertical motion registers the *A* digit of the office code. Its wipers then rotate to find an idle *BC* register. The latter responds to the *B* and *C* digits of the office code, and connects the circuits to the translator *Trans.* which is associated with it for that particular set of bank contacts.

The dialing of the terminal number is now switched to the magnets of the registers, *Th*, *H*, *T*, and *U*.

Upon completion of dialing the *ABC* digits, the translator at once sends back through other wipers of the *BC* and the *A* registers the complete designation of the directive which will guide the call to the desired office and line. This directive is delivered to the storage sequence switch 4 wipers, which guides each digit to its group (four relays each) where it is held by the locking up of the relays which were energized. The output contacts of each group of four relays are represented by a delta-shaped symbol at the right of each, which contacts lead into the common decimal multiple cable. The directive may have few or many digits. See Figure 15 for the meaning of the symbol.

The result is that we have connected to the decimal multiple a number of settings equal to the four terminal digits and to the number of digits in the directive.

Now the apparatus below the dashed line may be disconnected, being needed no longer for the call which we are considering.

The sequence switch associated with the storage relays now takes control, connects a ground on the first directive setting, and starts the sender. The latter sends impulses into the loop leading to the first directive selector, which stops when the wiper arrives at the grounded contact. The stop relay ends the impulses and causes its sender sequence switch to influence the storage relays to ground the next directive setting. It results in the next directive being sent, with the number of impulses indicated by the existing ground on the decimal multiple. In the same way all the rest of the directive digits are sent.

In like manner the terminal registers controls the impulses in its digit, until the entire number has been transmitted. At this moment, the wipers of the connector in the distant office are resting on the contacts of the called line. The events which follow are common knowledge.

Translation and Storage

The circuit device which forms the foundation is illustrated by Figure 15. Consider the four relays at the right and their contacts, mostly arranged in series with each other. If all four are energized, there is no path from the grounded spring to the sender bank. If all four relays are normal, there is a path from the grounded spring to the skip wire, which leads to that bank of the storage sequence switch to whose wiper the motor magnet is attached by its self-vibrating contact. It enables fewer directive digits to be used than the maximum provided.

Now consider the three relays at the left, and their contacts. Each relay has four main springs, one for each of the relays at the right. But the main springs are

Figure 16. From translator through storage into decimal multiple

grounded according to a plan. If we should press the key *M*, relay *M* would ground and operate relays *W* and *Y* at the right. Now trace the path from the main spring of relay *W* downward to the sender bank—the number 3 contact is grounded. Hence, if the sender moves its wipers as usual, the stop relay will pull up when the wiper reaches number 3.

Notice that the transfer of information is practically instantaneous—the storage relays pull down together.

If we had pressed the *N* key, it would have grounded contact number 2 on the sender bank. Likewise the *O* key would have grounded the number 8 contact. Thus by pressing any key we can cause the sender to send a certain number of impulses before being stopped. Reference to Figure 7 will recall the action.

The complete code is this:

Relays operated	*W*	*WX*	*WY*	*WZ*	*X*	*XY*	*XZ*	*Y*	*YZ*	*Z*
Digit produced	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*	*9*	*0* or *10*

It will be observed that the four wires between the *MNO* relays and the *WXYZ* relays are few enough to permit much switching without too many wipers. This is needed, for these four wires must be carried back (Figure 14) through the banks and wipers of the *BC* register, the *A* register, the *A* register hunter to the storage relays which feed into the decimal multiple into which the sender bank is wired.

To make possible later diagrams I will use the symbol at the right in Figure 15.

The essentials of the transfer of a translation to the storage relays are shown in Figure 16. I am assuming that the directive has only three digits, *M*, *N*, and *O*, represented by the relays at the left. Beside their operating contacts, each of them has four main springs, corresponding to the four wires, *W*, *X*, *Y*, and *Z*—the basis of the transfer code.

At the right are the storage relays, three groups of four relays each. Each group, such as the *M* group, has four relays, *W*, *X*, *Y*, and *Z*. The right hand winding of each with its contact enables each to lock itself energized. The left hand windings are the pull-up windings, by means of which the codes coming from the translator will operate such storage relays in each group as the desired decimal digit requires. It is the storage sequence switch which delivers the code for each digit to its own group of relays.

In the translator, the three relays *M*, *N*, and *O* must be caused to operate and release in sequence, so that each may ground the desired wires. At the bottom I have shown a small connecting block, by means of which the four main springs of each relay may be wired to the ground bus bar to make the code. For instance, suppose that the necessary directive is *325*. Thus when relay *M* pulls up, it must ground wires *W* and *Y*, shown by the dotted line on the block. Likewise, relay *N* will momentarily ground the *W* and *X* wires. Then relay *O* will momentarily ground the *X* wire alone.

By a control circuit not shown, the storage sequence switch will step its wipers along. When relay *M* is pulled up, the wipers of the sequence switch will be resting on their first contacts, leading to the four storage relays in the *M* group. Hence only relays *W* and *Y* will be pulled up and lock. The contacts represented by the delta-shaped symbol (Figure 15) will connect spring *m* to wire 3 in the decimal multiple.

When relay *N* in the translator (Figure 16) is taking its turn, the wipers of the sequence switch will be resting on their second contacts, leading to the relays in the *N* group. Thus relays *W* and *X* will operate and lock. When relay *O* in the translator takes its turn, the sequence switch will guide the ground connection to relay *X* in the *O* group, storage.

The sequence operation of the *M*, *N*, *O* relays in the translator is accomplished as follows. When the *BC* register stopped its wipers on the set of contacts, relay *14* pulls up in series with a relay in the *BC* switch. Relay *14* pulls the armature of the vibrator, *Vib.*, and holds it there, operates relay *M*, and pulls up relay *15*. The latter locks itself, grounds the holding circuit for relay *M*, and cuts off relay *14*. On falling back, relay *14* releases the vibrator armature, which, being weighted, swings back and forth like a pendulum. Its first swing to the left pulls up relay *PU*, which grounds the translator block bus bar and energizes the weak winding of relay *N*. Relays *M*, *N*, and *O* are of the 2-step type. Hence, relay *N* closes only its "weak" contact. When the vibrator causes *PU* to release, the short circuit is removed from the "in" winding of relay *N*, which promptly operates and locks itself to the ground on relay *15*. Relay *M* falls back and the code wires are grounded by relay *N*.

The same operations take place during the next closure of the vibrator, operating relay *O* and releasing relay *N*. This permits the *O* relay to have its chance at the code wires.

The last digit of the directive having thus been stored, the circuits are cut off at

the sequence switch, so that the *A* register, *BC* register, and translator are released and return to normal, ready to be seized by another call.

In the storage sequence switch, the *Z* wiper is switched to a circuit where it gets ground. From here this part acts like a sender sequence switch, working with the sender (Figure 14) in applying ground to each of the directive springs, *m*, *n*, and *o* in turn, and afterward to the wipers of the line register, *Th*, *H*, *T*, and *U* in succession.

Incidental Functions and Services

Not all calls go through with the regularity which I have assumed. Some of the following incidentals must be expected:

1. The subscriber removes the handset but does not dial.
2. He dials only part of the call number and then stops.
3. He dials a nonexisting office.
4. He dials a dead line number.

There is not room here to describe all these details, but adequate means have been provided. The first two are handled by a slow time device, which comes into play if any director is held longer than a set limit, after which the connection is released. Number 3 is run off to an information desk. The fourth is handled on the banks of the connectors as now done in automatic exchanges.

Trunking to manual offices, which have call indicators to display the number in front of the operators, is handled by inserting a coder in the trunk beyond the first selector, or a later selector. This changes the decimal digits into the kind of code used and sends it to the manual switchboard. Thus it does not affect the structure of the director. Incoming calls from manual to automatic are sent by the operator using some kind of calling device, either the push-button type or the dial type (for small manual boards). Such calls go directly into the automatic switches—the Director is not involved.

Enough has been illustrated and described to show rather conclusively that some kind of translating device can be made which will, from any office code, pick out any prescribed decimal number, and that this can reliably control an impulse sending device. Communication engineering is especially rich in devices and combinations. These being true, we need not care very much how the interoffice selectors are arranged, or how the multioffice exchange is laid out. We can make the complete Director assembly do whatever is necessary to direct a call to the desired distant office and to connect with the desired telephone.

An X-Ray Thickness Gauge for Hot-Strip Rolling Mills

C. W. CLAPP
NONMEMBER AIEE

R. V. POHL
MEMBER AIEE

THE EQUIPMENT described in this paper was built to fill a long-felt need in hot-strip steel-rolling mill practice. Heretofore, all gauging of the strip thickness has, of necessity, been delayed until the strip has cooled to a temperature where measurement by a hand-held micrometer is possible. In this length of time a modern high-speed mill may roll six or more tons of steel. Any error in mill setting resulting in an off-gauge strip is therefore very costly because of the large amount of off-gauge material produced before the error can be corrected. The need for equipment to gauge continuously the thickness of the strip as it issues from the finishing stand has been obvious for some time.

By ordinary gauging standards, the conditions under which the thickness measurement must be made are somewhat unusual. In a typical steel mill, the strip may be travelling at speeds of 2,000 feet per minute or more out of the finishing stand. As it leaves the rolls it may vibrate vertically through an amplitude of several inches and to prevent the possibility of jams or "cobbles," the clear opening through the gauge should be at least 18 inches high. The temperature of the strip is ordinarily between 1,500 and 1,750 degrees Fahrenheit. Cooling water sprays deluge the strip and any nearby equipment.

Under these conditions, a successful solution to the problem has had to await the development of a new X-ray gauging technique which forms the subject of this paper.

Review of X-Ray Theory

X rays are electromagnetic radiations lying in the wave length range extending from about 10^{-7} centimeter to about 10^{-12} centimeter. They are most readily produced by allowing a beam of high-speed electrons to fall on a target of some heavy element such as tungsten. When the electrons in the beam have an energy acquired by falling through a potential difference of V volts, the distribution in wavelength of the resulting X-ray energy is as shown in Figure 1, where λ_0 the shortest wavelength present, is given by

$$\lambda_0 = \frac{12{,}350}{V} \text{ angstroms} \tag{1}$$

where 1 angstrom unit $= 10^{-8}$ centimeters. These curves depicting the "continuous" X-ray spectrum[1] ignore the presence of any characteristic radiation emitted by the atoms of the target as this is an effect of which we make little use at present. The total X-ray energy radiated varies approximately as the square of the accelerating voltage V, directly as the beam current I, and directly as the atomic number of the target material.

When a beam of X rays strikes a sheet of some absorbing substance such as steel, a part of the beam is transmitted through the sheet unchanged while the remainder is either absorbed within the sheet or is reradiated as scattered X rays. When the incident beam is essentially monochromatic, the energy in the transmitted beam is given by the following equation

$$I = I_0 e^{-\mu x} = I_0 e^{-(\mu/\rho)\sigma} \tag{2}$$

where

I_0 = energy in incident beam
I = energy in transmitted beam
x = thickness of absorber (centimeters)
μ = absorption coefficient (per centimeter)
ρ = density of absorber (grams per cubic centimeter)
(μ/ρ) = mass absorption coefficient (square centimeter per gram)
$\sigma = (\rho x)$ = surface density of absorber (grams per square centimeter)

The mass absorption coefficient (μ/ρ) which appears as a constant in equation 2 is in turn a function of the wave length of the X rays and of the kind of atoms composing the absorbing material. Figure 2 shows the way in which the coefficient varies with wavelength for a few typical materials. Within regions which do not include a discontinuity, the mass absorption coefficient varies approximately as the cube of the wave length (λ), and approximately as the cube of the atomic number (N) of the absorbing atoms.

As yet we have said nothing about the means used to detect and measure the energy in the X-ray beam, though this is, of course, a matter of prime importance. Considering such qualities as sensitivity, speed of response, spectral response, long life, and convenient operation, a very satisfactory detector can be obtained by the use of a phosphorescent screen directly in front of a sensitive phototube.

Such a detector was used to obtain the data for Figure 3 which shows the intensity of the X-ray beam transmitted through different thicknesses of a standard low-carbon steel for several values of voltage V applied to the X-ray tube. In this case, the tube was operated directly from a 60-cycle high-voltage transformer and V represents the peak value of the voltage across the tube during the half-cycle when the target is positive with respect to its cathode.

The curves of Figure 3 are basic to the design of a thickness gauge for the material in question. They show for example that for a particular steel thickness and tube voltage represented by the point A, a 10 per cent decrease in tube voltage has

Paper 48-100, recommended by the AIEE mining and metal industry committee, the industrial control committee and the joint subcommittee on electronic instruments, and approved by the AIEE technical program committee for presentation at the AIEE winter general meeting, Pittsburgh, Pa., January 26–30, 1948. Manuscript submitted November 10, 1947; made available for printing December 16, 1947.

the same effect on the detector as a 27 per cent increase in steel thickness. Effective means must therefore be found to stabilize or compensate for changes in tube voltage to secure a reasonable accuracy in gauge reading. The curves also show that for a given small change in steel thickness the corresponding change in detector reading is not constant but decreases in general as the thickness of steel is increased. This behavior complicates the design of a gauge having a linear scale over a wide range of thicknesses. In the gauge to be described, solutions have been found for these problems and a linear thickness scale has been obtained over the range from 0.04 to 0.19 inch of steel with an over-all accuracy of ±2 per cent.

Description of Gauge

A condensed description of the method of operation of the gauge will first be given with reference to the block diagram Figure 4, following which the more important features of the design will be discussed in greater detail.

Let us begin at the X-ray tube shown in Figure 4. Ports are provided in the enclosure for this tube to select two beams from the total radiation to be designated as the reference beam and the measuring beam respectively.

The reference beam first passes through a long wedge of absorbing material (standard wedge), then falls on radiation detector number 1. The output of the detector is a direct voltage whose magnitude and polarity are a measure of the difference between the intensity in the reference beam and a standard reference intensity established within the detector for comparison purposes. The output voltage of this detector is used to control an electronic-voltage regulator in the primary circuit of the high-voltage transformer supplying the X-ray tube. By thus automatically controlling the voltage on the X-ray tube, the intensity in the reference beam is maintained at a level such that, after partial absorption in the standard wedge, it will have the value determined by the reference standard in detector number 1.

The measuring beam first passes through a thin wedge of absorbing material (measuring wedge) then through the thickness of steel to be measured and falls on the radiation detector number 2. Again the output of this detector is a direct voltage measuring the difference between the intensity of the beam striking the detector and a standard reference intensity established within the detector for comparison purposes. The output voltage of this detector is in turn used to control a motor geared to the measuring wedge. When the intensity in the measuring beam is different from the reference intensity, the motor shifts the wedge in a direction to increase or decrease the absorption in the beam as required to maintain the intensity at the value determined by the reference standard in detector number 2.

In operation, the reference standards in the two detectors are adjusted so that the measuring wedge comes to rest when the total absorption in the path of the reference beam equals the total absorption in the path of the measuring beam By making both wedges of steel, the thickness of the unknown steel sample can be obtained simply as the difference between the effective thickness of the two wedges. To provide a simple means of reading the gauge, the positions of the two wedges are transmitted through separate "selsyn" systems to two-scale pointers on a remote-indicator panel. One of these pointers, connected to the standard wedge, indicates the nominal steel thickness to which the gauge is set. The second pointer, connected to the measuring wedge, indicates on a zero-center scale the deviation in sample thickness from the nominal gauge size.

To set the gauge to a different value of nominal steel thickness, the standard wedge must be moved to present a different thickness to the reference beam. This is done by means of a small reversible motor controlled by push buttons on the remote-indicator panel. The same motor is also linked through a cam-mechanism to the arm of a variable-ratio autotransformer connected in the primary of the X-ray high-voltage transformer. As the standard wedge thickness is altered, the voltage on the X-ray tube thus is adjusted automatically to the approximate value needed to maintain the required intensity in the reference beam

Figure 3. Absorption of X rays in steel with tube operated at various alternating potentials

striking detector number 1. The range over which the electronic-voltage regulator must supply correction is thus greatly reduced.

In describing the general operation of the gauge, we have touched only lightly on two circuit features which will now be discussed more fully.

The circuit of the radiation detector is shown in Figure 5. This employs a 931-A multiplier-type phototube with a thin layer of silver-activated zinc-sulphide phosphor cemented to the outside of the phototube envelope opposite the cathode surface. When excited by X rays, this phosphor emits light having most of its energy at a wave length of 4,350 angstroms. Since the 931A phototube has its peak response at 4,200 angstroms, this makes a reasonably sensitive combination. Phototubes of this type vary widely in sensitivity but average tubes so coated have been found which when placed in a beam of 50 milliroentgens per hour gave a signal 30 decibels above photo tube noise. For these tests, the X-ray tube was operated in a half-wave self-rectifying circuit at a voltage of 40-kv peak value and the signal was measured in terms of peak-to-peak value.

As a radiation detector, the phototube-phosphor combination has the advantages of high sensitivity, high speed of response, and reasonably long life, and it does not require the maintenance of very high resistance circuit elements as does the ionisation chamber method. On the other hand, the sensitivity of the multiplier-type phototube varies rapidly with changes in electrode voltage, and is somewhat subject to fatigue effects.[2]

These disadvantages have been overcome in the present detector by requiring only that the phototube compare the relative strengths of two light signals and indicate which of the two has the greater intensity. The first of these signals is that due to the excitation of the phosphor by the X-ray beam and consists of rather sharply peaked half-wave pulses occurring at line-voltage frequency. During the half-cycle when the voltage on the target of the X-ray tube is negative, no X rays are emitted and the phosphor is dark. The second light signal is obtained from a glow-discharge lamp of a type recently developed for light-modulator service. This lamp is connected to the 60-cycle line through a ballast resistor as shown in Figure 5, and is shunted by a diode rectifier to ensure its excitation only on the alternate half-cycles of line voltage when no X rays are being emitted. The light from this lamp, after being suitably attenuated through filters is directed through the phosphor onto the cathode of the phototube. The signal out of the phototube therefore has the wave shape shown at the top of Figure 6 where the peaks are alternately related to the X-ray beam and to the reference light source. Since it is the peak value of X radiation that is most significant, it is the peak values of these two signals that are compared. Their wave shapes are otherwise unimportant.

To compare these peaks, the signal from the phototube is first amplified through a linear amplifier, then applied to the grids of the phase-sensitive triode detectors as shown in Figure 5. In this circuit, the plates of the two detector tubes are supplied with voltages of equal amplitude but opposite phase through a center-tapped transformer connected to the 60-cycle line. The cathode-load resistors R_1 and R_2 are made very large compared with the reciprocal of the mutual conductance for the triodes and the capacitors C_1, C_2 are selected so that the time-constants $R_1C_1R_2C_2$ are long compared with the period of the signal wave. Under these conditions, the capacitors C_1 and C_2 charge up to steady voltages V_1 and V_2 sufficient to maintain their respective tubes close to or beyond plate current cut-off at all times. If we designate the a-c component of the voltage applied to the grids of the tubes in parallel by e_g, and the a-c component of the plate voltages by e_{p1} and e_{p2} as shown in Figure 6, then we have the condition that

$$e_g - V_1 + (1/A)(e_{p1} - V_1) = 0 \qquad (3)$$

and

$$e_g - V_2 + (1/A)(e_{p2} - V_2) = 0 \qquad (4)$$

where A is the amplification factor of the triodes.

Figure 4. Block diagram of X-ray thickness gauge

Figure 5. Circuit diagram of radiation detector

$V_1(1+1/A)$ is equal to the maximum value of $e_g+(1/A)e_{p1}$

$V_2(1+1/A)$ is equal to the maximum value of $e_g+(1/A)e_{p2}$ ■

Remembering that the plate voltage on one of the triodes, say e_{p1}, has its maximum value when the signal from the X-ray beam is a maximum, and that the plate voltage on the second tube (e_{p2}) reaches its maximum in phase with the signal from the reference light source, it can be seen that V_1 and V_2 are linear functions of the peak values of the X-ray signal and the reference light signal respectively. The output of the detector, consisting of the voltage (V_2-V_1), is therefore zero when the two signals have equal peak values and at other times has a value proportional to the difference between the two signals.

The circuit diagram for the electronic regulator used to control the accelerating voltage on the X-ray tube is shown in Figure 7. This regulator operates by varying a resistance element connected in series with the primary of the high-voltage X-ray transformer.[8] The resistance element consists of the plate resistance of four 807 tubes connected in parallel. The transformer T_3 serves to provide a proper impedance match between the plate circuits of the tubes and the power-line circuit into which they operate. To utilize the 807 tubes efficiently, their screens are maintained at a steady d-c potential. The grid bias on the tubes is controlled by the output of radiation detector number 1 amplified through one stage of d-c amplification. When connected as shown the tubes carry current only on one half-cycle of the line voltage, this of course being the half-cycle during which the X-ray beam is emitted. The resistor R serves a dual purpose; it limits the voltage appearing across the tubes on the negative half-cycles of voltage and during the warm-up period of the tubes, and it increases the regulating range of the circuit as will be shown in the simple analysis to follow.

As normally operated, the current through the X-ray tube is limited by the emission of the cathode. We will therefore make the simplifying assumption that the current drawn by the high-voltage X-ray transformer has the constant value I_L during the positive half-cycle of voltage and is zero during the negative half-cycle. While the line current I_L is flowing, let I_R be the current through resistor R, and $E_R=RI_R$ be the voltage across R, and let I_p be the total plate current through the regulator tubes. If the transformer T_3 has the turns ratio n, and we neglect losses in this transformer, then $I_L=I_R+nI_p$, and the voltage on the plates of the regulator tubes is $E_p=nE_R$.

Figure 8 shows the various currents and voltages involved referred to the high-voltage side of transformer T_3.

Figure 9 shows the plate characteristics for an equivalent regulator tube. Since four *807*-type tubes are used in parallel, this is obtained from the characteristics of a single tube by multiplying the current values by four. The permissible region of operation of the tube is bounded by the heavy line *O-a-b-c-d-O*. The boundary *c-d* is determined by the maximum voltage that can be allowed across the tubes and transformer. The boundary *b-c*, a segment of a rectangular hyperbola, is determined by the maximum dissipation that can be allowed at the plates of the regulator tubes. In drawing this, it should be remembered that plate current flows only during one half of the cycle. The boundary *O-a-b* follows the curve of zero grid bias for the particular value of screen voltage used, since insufficient power is available in this circuit to drive the grids positive. The screen voltage on the tubes was limited in this instance by screen dissipation.

Since the plate current in the equivalent regulator tube is given by

$$I_p=(1/n)(I_L-I_R)=(1/n)(I_L-E_p/nR) \quad (5)$$

the various possible operating points lie along a straight line which we shall call the "load line" by analogy with conventional amplifier analysis. Since n and R are as yet undetermined, we are free to select both the slope of this line and its intercept on the plate voltage axis. Let the load line intersect the plate voltage axis at the maximum allowed plate voltage E_a, and let its slope be such that it intersects the boundary *O-a-b-c* at the point corresponding to the voltage E_1 and the

Figure 6. Voltages in phase sensitive detector

current I_1. Its intercept on the plate current axis is then the point I_L/n corresponding to full line current referred to the high voltage side of transformer T_3.

Let the total power dissipated in R and the regulator tubes be W_1 when the operating voltage has its minimum value E_1 and let it be W_2 when the operating voltage has its maximum value E_2. Our problem is then to adjust the slope of the load line so that $(W_2 - W_1)$ is a maximum. It can be shown that

$$W_2 - W_1 = (E_2 - E_1)I_L/n = E_2 I_1 \qquad (6)$$

hence I_1 should be as large as possible.

From practical considerations, a good choice is made by passing the load line through the point a just above the knee of the zero-grid bias curve. The intercept of this line on the plate current axis then determines the proper transformer turns ratio n and the slope of this line determines R through the relation $R = E_2/nI_L$.

In the regulator here described, I_L had the approximate value seven amperes, and suitable values for R and n were 8 ohms and 14, respectively. With these values, the voltage E_R across R could be controlled over the range extending from 15 to 35 volts. Hence an error in input voltage of ±10 volts can be corrected by this regulator and this range is ample. The sensitivity of the detector and d-c amplifier is such that a change in input voltage of ±5 volts produces a change of only ±0.001 inch in gauge reading. To reduce further this and other sources of error, all 60-cycle power for the gauge is obtained through an auxiliary regulator which maintains the line-voltage constant to within ±1 volt. The only troubles encountered in putting this circuit into operation were from parasitic oscillations in the parallel-connected regulator tubes. These were best eliminated by connecting a 2.5-millihenry choke in each of the four plate leads.

Operating Performance

Figure 10 shows the component parts of the gauge as installed at the Irvin works of Carnegie Illinois Steel Corporation.

The large unit near the bottom of the photograph houses the X-ray tube and associated high voltage and filament supply. These are contained in a lead-lined oil bath, with forced-oil circulation to the anode of the tube and separate water cooling of the oil. The tube used has a tungsten target and is rated at 100-kilovolt peak. Also contained in this unit are the two steel wedges mentioned previously, with their associated motor drives and connected "selsyn" transmitters, and the phototube and reference light source for detector number 1.

The phototube and reference lamp for detector number 2 are mounted in a separate water-cooled steel housing shown near the top of the photograph. At installation, this unit is mounted about 24 inches above the lower unit and is centered in the measuring beam which is directed vertically upward from the lower unit.

The cabinet shown at the right houses the remainder of the electronic detection and control equipment as well as the power supplies for all circuits.

The unit shown at the left is the remote indicator. Its lower dial indicates the nominal gauge size in thousandths of an inch, while the upper dial indicates the deviation of the steel thickness in thousandths of an inch from the nominal size. Means are provided at the indicator station to correct the calibration of the gauge when necessary and to select any nominal gauge size within its range.

There are certain points that should be considered in using a gauge of this type

Figure 8. Load circuit for equivalent regulator tube referred to high-voltage side of transformer

Figure 9. Plate characteristics of equivalent regulator tube showing location of load line

which are related to the operating conditions. Among these we can list the effect of impurities or changes in composition of the steel, the additional absorption of the layer of cooling water retained on the steel strip, and the contraction of the steel in cooling down to room temperature.

Fortunately, most of the alloying elements commonly used in making steel have an X-ray absorption coefficient less than or only slightly greater than that of iron. Tungsten and molybdenum are the principal exceptions to this statement, but are not commonly used in sheet steels. Stainless steel of the common 18–8 composition has an absorption coefficient within 1 per cent of that of iron at room temperatures, and this small difference can be readily taken care of by a zero adjustment during calibration. For common grades of silicon steel the correction may amount to seven per cent. The gauge dial of a gauge used for measuring several alloys has several concentric scales.

Large quantities of water ordinarily are used to cool the finishing rolls and the strip as it emerges from the finishing stand and consequently water-puddles an eighth of an inch in thickness will frequently be found on the strip at the measuring point.

A continuous water layer 1/16 of an inch thick can cause an error of 0.0006 inch in steel thickness when the steel is 0.06 inch thick and an error of 0.0016 inch when the steel is 0.18 inch thick. The difference is due to the change in voltage applied to the X-ray tube for these two conditions. Where this is objectionable, the water can be removed from the measuring point by a strong air-blast.

Figure 7. Circuit of electronic voltage regulator

Figure 10. General Electric X-ray thickness gauge for hot strip steel mill

While the steel is being gauged, its temperature is in the neighborhood of 1,600 Fahrenheit. As compared with the same steel at room temperature, the hot strip presents fewer iron atoms in a given cross-section of the X-ray beam and hence gives a lower reading of thickness. The correction for temperature depends only on the expansion coefficient of the steel, and for ordinary carbon steels amounts to 1.6 per cent per 1,000 degrees Fahrenheit. Since the rolling temperature is usually known to within ±200 degrees, it is a simple matter to graduate the scales to correct for this error.

Safety Considerations

In a device of this type intended for use by nontechnical personnel, the question of safety must be given full consideration. Our approach to this problem has been threefold. First, the unit containing the X-ray tube has been built to conform to the requirements for a Class I or fully protective housing as defined in the proposed ASA Safety Code for the Industrial Use of X-Rays (*Z54.1–1946*). This means that, except for the measuring beam itself, the radiation from this unit is everywhere below the level at which it could cause harm to personnel. Secondly, by using sensitive detection means, the X-ray intensity needed in the measuring beam has been kept as low as possible. While a measurement is being made, the beam intensity at the upper phototube unit is approximately 50 milliroentgens per hour. Scattered radiation from the beam is below tolerance level of 12.5 milliroentgens per hour at all points more than two feet away from the direct beam under all conditions of use. Thirdly, warning lights and barrier gates interlocked with the X-ray tube voltage supply have been provided at all points of access to the gauging area to prevent personnel from entering this area while the beam is on. As an additional precaution and check, it has been recommended that operating personnel carry monitor pencils until the safety of their work habits has been amply demonstrated.

Other Applications

The gauge described in this paper was designed to fill a specific need—that of measuring the thickness of hot-rolled steel strip. The method employed is however adaptable to many other gauging problems where a noncontacting gauge is desired. One such application on which we are actively engaged is the gauging of cold-rolled steel strip where, because of the speed of the strip, the accuracy of contacting methods of gauging is reduced. The method can also be used with metals other than steel, and with various nonmetals. In all these applications, however, we must consider whether there is present in the material, in any appreciable quantity, an element whose absorption coefficient is greater than that of the element used as the basis of gauging. If such is the case, the thickness reading obtained on the gauge will depend on the relative amounts of the two elements present.

For example, the aluminum alloy designated as *24ST* contains approximately 4.5 per cent of copper. Unless care is taken to keep the X-ray tube voltage below

approximately 9-kv peak value, it will be found that this amount of copper is responsible for up to 35 per cent of the total absorption coefficient. A change of 1 per cent in copper content would therefore be read as a 9 per cent change in thickness, or alternatively, to obtain an accuracy of 2 per cent in thickness reading, it would be necessary to know the copper content to within ±0.2 per cent and to make appropriate correction. This could be accomplished by readjusting the zero of the gauge with a sample of proper thickness and composition in the beam. This alloy is perhaps the most difficult of the common aluminum alloys to gauge by this method, many of them presenting no problem in this respect.

To take another example, automotive gasolines contain tetraethyl lead in quantities up to 0.2 per cent by weight. At X-ray voltages in the neighborhood of 40-kv peak value, this amount of lead is responsible for over 25 per cent of the total absorption of this liquid. In this case, the X-ray gauge would be useless as a thickness gauge unless the lead content were accurately known. On the other hand, by-passing the liquid through a chamber of known depth, the method can be used to measure the percentage of lead present in the gasoline[4] with sufficient accuracy to make this an attractive method of analysis.

Amalgam-Cathode Materials for Power Tubes

J. A. M. LYON

Synopsis: The proper operation of ignitrons and other mercury-pool cathode tubes of conventional design may be impeded where these tubes are subjected to vibration, tipping, or rapid acceleration. These factors would, in general, be present in installations in electric locomotives, ships, or military tanks. In some cases arc-backs or loss of control would be caused by motion of the mercury. Many of the uses of the mercury-pool cathode tubes are predicated on the copious electron emission of mercury. It has been the aim of the research described in this paper to obtain a cathode which retains the tremendous emission capabilities of mercury and yet is mechanically rigid so that jarring or tilting of the tube does not affect the operation of the tube.

EARLY in this work it appeared that an amalgam would have the desired emission characteristics and the proper amalgam would have sufficient mechanical rigidity so that a tube could operate under rough usage involving rotating, inverting, or shaking of the tube. The first part of this problem is concerned with the materials and proportions for a suitable amalgam cathode and the second consists of devising a satisfactory mechanical arrangement for the tube elements, as well as providing a means of controlling the conduction of the tube. The amalgam cathode must be rigid and stable under the action of a cathode spot. Mercury is continually vaporized from the cathode spot and will condense upon the relatively cool walls of the tube. It is desirable to have an amalgam where any other vaporized constituent of the amalgam will be washed from the walls of the tube by the mercury and at the same time a reamalgamation will take place. These droplets of mercury and amalgam will be returned to the cathode and there reform into a solid amalgam. A further requirement of an amalgam cathode tube is that it compares favorably with conventional ignitron tubes on the basis of efficiency, overload capacity, useful life, ease of control, and ability to withstand inverse voltages without reverse conduction taking place.

Dentistry is probably the largest user of solid amalgams at the present time. Considerable information[1] is available on the hardness, setting time, composition, and resistance to corrosion of various dental amalgams. The majority of these contain a high proportion of silver. General information about amalgams is available in some chemical reference books,[2] and metallurgical texts.[3]

Very little has been published on the electrical properties of solid amalgams. Newman[4] has investigated the spectra of some alkali-metal amalgams; this work involved a glow discharge and at no time did he consider arc discharges. However, his work showed that the yellow lines of sodium were always present in the spectra of sodium-amalgam glow discharges. Very likely the amalgams used were liquid. Arons[5] studied the spectra and cathode drop of several metal amalgams. Arons' data on sodium amalgams are incomplete although he listed a cathode fall of 20 volts and stated that it was less than for mercury alone.

Amalgams which contain more than 99 per cent mercury are generally fluid at room temperature. Superficially, at least, this rules out the use of materials which have a very low solubility in mercury. Copper, iron, calcium, bismuth, antimony, aluminum, arsenic, and nickel have low solubility in mercury.[3]

The amalgam of sodium has some interesting properties which may allow the cathode to be replenished. An examination of the freezing point curve in Figure 1 shows that amalgams containing very high or medium percentages of mercury are liquid at temperatures of 50 Centigrade or less. Furthermore, amalgams containing from two to ten per cent sodium are solid at 250 Centigrade. Mercury vapor is continually condensing upon the walls of a tube and rolling back to the cathode. It is conceivable that if mercury and sodium deposited on the walls in any proportion greatly different from six per cent sodium, then the deposit would liquefy and return to the cathode.

The experimental equipment used in the research was composed of a vacuum system including a mechanical roughing pump, a two-stage mercury diffusion pump, a cold trap, and a McLeod gauge. Experimental tubes were connected to this vacuum system. A pressure of 0.1 micron was the lowest obtained during any of the experimental work.

Tin amalgam was utilized in the first attempt to form a cathode spot on a solid surface. Slepian[6] mentions that an ignitor rod cast into a tin surface would form a cathode spot even at atmospheric pressure. Preliminary tests showed that a 35 per cent tin amalgam was rigid, although what appeared to be a liquid phase could be shaken out of it. A d-c power source was connected to the tube containing tin amalgam, and a cathode spot started after a positive pulse was applied to the ignitor. The spot was self-maintaining and moved erratically over the solid cathode surface. The arc drop fluctuated rapidly within a range from 8 to 17 volts.

The cathode surface appeared bright and shiny where it had been traversed by the cathode spot. After a few minutes of operation the glass walls became covered

Paper 48-102, recommended by the AIEE electronics committee and approved by the AIEE technical program committee for presentation at the AIEE Great Lakes District meeting, Des Moines, Iowa, April 1-3, 1948. Manuscript submitted January 19, 1948; made available for printing February 26, 1948.

J. A. M. LYON is associate professor of electrical engineering at Northwestern University, Evanston, Ill., and C. E. WILLIAMS is assistant research engineer, Standard Oil Company of Indiana. The experimental data in this paper have resulted from the research by C. E. Williams in partial fulfillment of the requirements for the degree of master of science from Northwestern University.

with an opaque, grayish deposit. This was probably tin sputtered from the cathode surface and oxidized partially by the leakage of air into the tube. The deposit would not melt at the softening point of Pyrex glass.

The next tube was built in a 500 cubic centimeter Pyrex flask and tested with a 50 per cent lead amalgam. The ignitor was a one-eighth inch carbon rod of approximately two ohms total resistance. A cathode spot could not be started, even with a 1,000-volt, 4-millicoulomb positive pulse applied to the ignitor. The ignitor resistance was evidently too low. A spot started readily when the terminal of a high frequency leak-tester was held against the glass. This tester would produce a low intensity one-inch spark in air. Data obtained with this tube are shown in Figure 2. This tube was also operated on 230 volts alternating current and conduction was started near the positive peak of each cycle by holding the leak tester against the glass. The arc drop appeared to vary inversely with current when viewed on a cathode-ray oscilloscope. This is in agreement with the d-c curve shown in Figure 2. The inner walls of this tube became coated with a bright film of sputtered metal. The thinner sections were semitransparent. The amalgam appeared bright where it had been subjected to a cathode spot. The film formation on the walls of the tin-amalgam and lead-amalgam tubes indicated that a considerable amount of material was being sputtered off the cathode. It is undesirable to have this depletion of the cathode since it would shorten the life of the tube.

A mercury-pool cathode ignitron, with a spacing of approximately $2^1/_2$ inches between anode and cathode, was built so that its arc drop could be compared with that of amalgam-cathode tubes. This tube had an arc drop of 15 volts while carrying a direct current of six amperes.

Figure 2. Arc drop of tubes with solid-amalgam cathodes

Experimental work was next conducted on sodium-amalgam tubes. There are several difficulties involved in preparing sodium amalgams. Sodium and mercury form definite compounds and considerable heat is evolved during amalgamation. If a piece of fresh sodium is removed from kerosene and dropped into mercury, a small explosion results. Probably the heat of formation ignites the kerosene. Mellor[3] states that the heat of formation of sodium amalgam is 20 calories per gram. Some amalgam mixed for use in a tube reached a temperature of over 200 degrees centigrade. The resulting mercury fumes are dangerous.

An attempt was made to form sodium amalgam by distilling mercury into sodium under vacuum. This failed when the glass chamber was broken while attempting to seal in the sodium. The method ultimately used was to cut the sodium into one-fourth inch cubes, wash them in water-free ether, and then drop them at intervals into a crucible of mercury. The amalgam sets immediately to a rigid mass. After cooling it is nearly as hard as lead and more brittle. This amalgam is readily oxidized and will decompose water slowly. This offers a ready means of cleaning it. The sodium breaks down the water and forms a solution of sodium hydroxide. The excess mercury forms a shiny protecting layer over the remaining amalgam. Samples of two per cent sodium amalgam left under water for 20 hours had apparently lost all of the sodium content. Sodium amalgam has a pronounced effect upon metals which are not ordinarily amalgamated by direct contact with mercury. Touching steel, nickel, Kovar, or aluminum to clean sodium amalgam will amalgamate them. However, the use of a stainless steel grid in a later tube indicated that sodium amalgam had no tendency to amalgamate with stainless steel. This means that tubes with stainless steel jackets could be utilized for tubes having sodium amalgam cathodes.

A sodium-amalgam tube was built in a 200 cubic centimeter Pyrex flask. The composition of the amalgam was approximately six per cent sodium and 94 per cent mercury. The amalgam was broken into small lumps with a hammer, and dropped into the tube. The rough pile of lumps shorted out the ignitor rod and conduction was started by holding the high-frequency leak-tester against the glass.

The arc-drop of the tube varied greatly with pressure. At 1 millimeter pressure the drop was 50 volts, while at 0.5 micron the arc drop fell as low as seven volts. The curves in Figure 3 show the characteristics of this tube. After operating a short time the walls of the flask became covered with a grayish deposit. The cathode spot left the cathode surface and traveled over this deposit. The spot cut a jagged path through the deposit and left only a thin gray film upon the glass. The spot glowed a deep yellow and heated the glass beneath it.

The spot traveled rapidly over the glass walls, ranging in position from the cathode surface up to any point within one-fourth inch of the anode lead. The amalgam lumps at the cathode did not melt at any time during the operation of this tube. At currents above five amperes two or more cathode spots formed on the wall at widely separated points. At twelve amperes four or more spots were erratically traveling about the inside of the tube. As a spot evaporated most of the coating from the glass, it traveled to a new and more thickly coated area. The tendency was for the spot to locate as near the anode as the thickness of the coating would permit.

This tube was sealed off the vacuum system at a pressure of 0.5 micron and performed without change when inverted.

Figure 1. Freezing point curve of sodium-mercury amalgams after Mellor[3]

Figure 3. Direct-current characteristics of a sodium-amalgam tube

A drop of fluid amalgam condensed in the sealed-off tube. This could be rolled over the deposit on the glass walls without appreciably wetting it. This indicates clearly that the deposit was not composed solely of sodium and mercury. Apparently the hot sodium reacted with the Pyrex glass.

A new four per cent sodium amalgam was tested in a Pyrex bulb approximately two inches in diameter and five inches long. A one-inch diameter graphite anode was mounted axially within $1^1/_4$ inches of the cathode leads. This tube was similar to the one sketched in Figure 4. The d-c characteristics of this tube are shown in Figure 2.

The ignitor was a silicon-carbide rod approximately one-fourth inch in diameter. The amalgam lumps were melted in the bottom of the tube by holding a gas flame against the glass. The walls of this tube also became coated with a grayish deposit. All except a very thin film of this could be evaporated off with a Bunsen flame. The cathode spot generally did not travel more than two inches from the cathode surface. At this level it was approximately one-half inch from the anode. After completion of the oscillograms for several a-c tests, the tube was cut open and examined. The gray coating was approximately one-sixteenth inch thick and highly conductive. A resistance of less than one ohm was observed between points one inch apart on the coating.

The foregoing tube was operated on an a-c power supply with the anode firing with a delay of approximately 30 degrees. The ignitron pulse circuit of Figure 5 was used in the firing of this tube. Oscillograms were obtained for the performance of this tube, but are not reproduced in this paper. A single cycle of reverse conduction was observed on one oscillogram while operating from a 230 volt a-c line. The arc drop during the a-c tests of this tube was approximately 15 volts. This is roughly twice the d-c value shown in Figure 2 for this same tube. The d-c values were determined with the cathode spot on the side wall of the tube approximately one-half inch from the anode. When operated on alternating current, the spot was started at the cathode surface by the ignitor. For a-c operation, evidently, the mobility of the spot was not sufficient to permit it to move off the cathode surface during the time the anode was positive. This gave an arc length over twice as long as when the spot was on the glass side walls.

All the amalgam cathodes tested so far have shown no sign of melting during operation. This indicates that the per cent

Figure 4. Experimental ignitron tube

of amalgamating metal could be reduced, which might cause the tube to perform as though it contained mercury alone. Another tube similar to the one sketched in Figure 4 was built up using a two per cent sodium amalgam. A stainless-steel grid, consisting of 0.136 inch holes drilled with a spacing of 0.176 inch between centers, was placed approximately one inch above the cathode surface. This was an attempt to reduce sputtering, as well as offering an opportunity of studying the distribution of charge at this point.

The waveform of grid current was observed on a cathode-ray oscilloscope while the anode carried a direct current of four amperes and seven volts alternating current was applied to the grid. The grid current appeared sinusoidal which indicates that there was a large supply of positive ions near the grid.

The grid seemingly had no effect on the amount of sputtering and maintaining it at the specified potential with respect to the cathode involved a considerable waste of power. The waveforms were very similar to those for the four per cent sodium-amalgam tube, except that ignitor currents were much greater and no reversed conduction occurred at any time. The ignitor in this tube was a boron-carbide rod.

Further tests of this tube were made with a 7.6 volt a-c potential applied to the grid in phase with the anode voltage. Electron current flows into the grid from the external circuit during anode conduction and oscillographic records show a grid current dip at the peak of its cycle. The arc drop of this tube was about 20 volts by d-c measurement. Most of the arc drop occurs near the cathode and causes the potential of the grid always to be greater than the applied 7.6 volt grid excitation. The difference will be least at the peak of the grid voltage and this would cause a decrease in grid current. This explanation accounts for the negative grid current and the dip near the peak of the grid current.

All of the tubes using sodium amalgams became blackened on the inside of the glass. Further effort is contemplated with sodium-resistant glass used commercially in sodium-vapor lighting equipment.

Magnesium amalgam was investigated to determine whether its higher melting point would make it less subject to sputtering. Magnesium does not react noticeably with mercury at room temperature. If the mercury is boiled in contact with magnesium chips, the amalgam forms in an explosive manner. The heat evolved may ignite part of the magnesium. The amalgam is very active. It decomposes water more rapidly than sodium amalgam and forms a black oxidized surface when exposed to air.

It was found that if the mercury and magnesium were placed in a tube and held under vacuum the amalgam formed slowly at room temperature. The heat evolved in the process of forming 100 grams of amalgam would keep the tube noticeably warm for 24 hours. The test data on a $5^1/_2$ per cent magnesium amalgam tube are plotted in Figure 2. The amalgam was very solid and appeared to have an excess of magnesium. Loose chips of magnesium lying on the cathode surface were blown about like dry leaves in a whirlwind by the vapor blast from the cathode spot. The tube walls did not become coated as rapidly or as completely as with the sodium amalgam. The cathode spot travelled over the walls near the cathode surface.

During the course of this work, it has been observed that all of the amalgams used oxidized readily. In all probability amalgamating the metals under vacuum would eliminate most of this difficulty; in future work, this will be a procedure to be tried. The experimental ignitron

Figure 5. Ignitor pulse circuit

shown in Figure 4 could conceivably be damaged by the expansion or contraction of the amalgam during the operation of the tube. However, cracking of the glass from this cause was not observed. Some modification of the design of the tube will be attempted in further work.

None of the tubes tested were evacuated to the degree that is obtained in commercial tube manufacturing. It is possible that some of the arc-drop curves were influenced by the presence of residual gas within the tube. Regarding the inverse voltage breakdown strength of the tube, it was observed that only the sodium-amalgam tube with heavily sputtered walls ever failed at less than 330 volts inverse peak voltage.

No measurements were made of the temperatures of the cathode or the side walls of tubes. A spectrometer was not available for the work up to the present time. At an early date it is desired to make an analysis of the composition of the vapors present in such tubes by use of a spectrometer. This procedure will shed light on the energy transformations which take place within the tube. In this connection, it should be mentioned that the formation of amalgams is very interesting from the thermodynamic standpoint. It has been noted that some of the amalgams studied were formed with considerable evolution of heat.

These experimental tests give some hope that the use of a solid-amalgam cathode will be feasible for power tubes, especially for those used in low-voltage circuits. The controllability and efficiency of amalgam-cathode tubes is comparable with that of conventional mercury-pool tubes. There is reason to believe that with proper sodium-resistant glass the sodium-amalgam power tube can be perfected so as to give electrical performance comparable with mercury-pool tubes, and yet possessing the mechanical advantages desired, as stated at the beginning of this paper.

It should be pointed out that the tests studied so far indicated that they are not sensitive to changes in position, such as a complete inversion of the tube. Obviously, for long time operation, the cathode could not replenish itself in the inverted position.

The General Solution Method of Power Network Analysis

LYLE A. DUNSTAN
MEMBER AIEE

Synopsis: The general solution method of power network analysis grew from the systematic investigation of the effects of changes in a power system being analyzed by mathematical methods. The investigation led to an improved method of computing load-flow studies by which successive approximations converging upon precise answers could be carried through without the solving of simultaneous equations, a method so flexible that changes in loads, ratios, phase shifts, or even the circuit offer no difficulties. The general solution, by taking advantage of a previously computed solution when computing a new solution, is particularly adapted to the computation of a family of solutions for a particular network. Investigation of the effects of changes indicated that the effect of a change in loading, transformer ratio, or phase shift upon any particular network answer could be closely approximated by multiplying the change by a coefficient. Similarly, the effect of a change in value of a circuit element, or the effect of a new circuit element added, upon any particular network answer could be approximated by multiplying a constant by a coefficient. This paper is concerned with the computation of the complete set of coefficients describing the effects of any loading, transformer ratio, phase shift, or circuit change upon any flow, voltage, or phase angle. The complete set of coefficients is termed in this paper the "general solution" to the network. Although the initial computation of the general solution for a large power system is a tedious process unless accomplished with punched-card machines or other automatic computing machinery, the application of the general solution, once computed, to innumerable system studies is extremely simple. The method makes possible the efficient handling of load-flow studies for power systems using no equipment other than a desk calculating machine. In addition to the facilitating of the making of load-flow studies, the general solution may serve to indicate the impedance between any two points in the system, either for fault purposes or for the determination of an "equivalent" for use in network analysis. Thus, the method should prove helpful for symmetrical components work. If general solutions have been computed for two adjacent systems, the effects of various interconnections between the systems may be readily evaluated.

General Flow Solution for Direct Current Problem

FOR illustrative purposes, the problem of determining the current in the simple network of resistances shown in Figure 1 is posed. This d-c problem is given as a first example because it is amenable to exact solution by classical methods, and because it illustrates the principles which are later applied to a-c power networks by suitable analogy and approximations. The problem illustrates how the general flow solution can simplify the computation of network current flows for any set of loads (currents supplied or withdrawn from the junctions), any voltage inserted at a particular point, a resistance changed to any desired value, and a new leg added to the network.

Consider the circuit shown in Figure 1, assuming the dotted circuit from A to D to be nonexistent, and the resistance of line AB to be 0.1 ohm. Initially, the problem is to determine the current flows throughout the network for any set of loads at points A, B, C, and D with the balance current made up at E, $E=-(A+B+C+D)$, and neglecting the effect of voltage V. Point E will be termed the "slack-take-up bus." The general solution to this problem is a set of coefficients to be multiplied by the loads, so that the sum of the products for each line is the line current flow. The set of coefficients for each load point is a set of distribution factors for a unit current supplied to the network at the load point and withdrawn at the slack-take-up bus. Although distribution factors may be computed either by star delta transformations or by simultaneous equations, such methods are relatively inefficient unless use is made of the computations for a unit current at one bus when computing for a unit current at another bus.

The circuit of Figure 1 is coded as shown in Figure 2 by assigning a positive direction of flow to each line and indicating the loops including each line. The circuit contains three loops, meshed so that no directional arrows conflict: loop 1 containing lines AB, BC, and CA; loop 2 containing lines BC, CD, and DB; and loop 3 containing lines AB, BC, CD, DE, and EA. Table I shows the lines in the circuit of Figures 1 and 2, the resistance of each line as taken from Figure 1, and the loops containing each line is taken from Figure 2. Since the summation of voltages about each loop must equal zero, simultaneous equations may be written, as shown in Table II, which illustrate that, if loop flows are taken as variables, the coefficients may be formed by summing the resistances by loops and by pairs of loops resulting in a symmetrical set. In Table II, ΣR_1 represents the summation of all resistances in loop 1, ΣR_{12} represents the summation of all resistances common to loops 1 and 2, and so for the other subscripts. I_1 represents current flow around loop 1, I_2 represents current around loop 2, and I_3 current around loop 3. Each equation contains a "K" term which is equal to all voltage in the loop not due to loop flows. By substitution of the values of resistance for each loop from Table I into the simultaneous equations of Table II, the simultaneous equations in the upper portion of Table III may be formed. For example, the I_2 coefficient in equation 2 (by symmetry this is also the I_2 coefficient in equation 3) is formed by adding all resistances from Table I which are in both loops 2 and 3, that is, 0.7, line BC, plus 0.4, line CD, equals 1.1.

Paper 48-103, recommended by the AIEE system engineering committee and approved by the AIEE technical program committee for presentation at the AIEE Great Lakes district meeting, Des Moines, Iowa, April 1-3, 1948. Manuscript submitted November 12, 1947; made available for printing February 2, 1948.

LYLE A. DUNSTAN is with the Federal Power Commission, Washington, D. C.

Figure 1. Circuit for d-c problem

The lower portion of Table III is a general solution for I_1, I_2, and I_3 in terms of k_1, k_2, and k_3. The set of coefficients of k_1, k_2, and k_3 is known mathematically as the inverted matrix of the set of coefficients of I_1, I_2, and I_3, and the Appendix gives a method of inverting a symmetrical matrix and a special type of nonsymmetrical matrix. The loop flows for any particular set of constants in the equations of Table III are equal to the sums of the products of the constants times factors from the inverted matrix, that is, I_1 equals $(-1.649\ k_1)$ plus $(0.599\ k_2)$ plus $(0.287\ k_3)$. Since currents supplied or withdrawn from the network at the junction points, and series voltages such as voltage V affect only the constant terms in the equations, the inverted matrix forms a basis for building a general solution for any current loads or series voltages.

Assume that a unit current flows from D to E in line DE and that circulating currents, of the proper magnitudes to balance voltage drops, flow around each of the three loops. Since line DE has a resistance of 0.5 ohm and is in loop 3 only, k_3 in the equations of Table III will equal 0.5 volts and k_1 and k_2 will equal zero. The loop flows for the condition equal k_3, or 0.5 times the k_3 column of the inverted matrix, or 0.1435, 0.2215, and -0.3735 for loops 1, 2, and 3, respectively. A unit flow through line CD, which has a resistance of 0.4 ohm and is in loops 2 and 3, will make k_2 equal k_3 equal 0.4 volts and k_1 equal zero, which will result in loop flows of 0.3544, -0.3676, and -0.1216 for loops 1, 2, and 3, respectively. If a unit current is supplied the network at D and withdrawn at E, the resulting currents may be assumed to be composed of components, a unit current through line DE, and loop circulating currents resulting from the unit current through line DE, as discussed earlier. If the unit current is supplied the network at C and withdrawn at E, the resulting currents may be assumed to be composed of components, a unit current through lines CD and DE, and loop circulating currents. The loop circulating currents for this case will equal the loop currents resulting from a unit current through line CD, plus those resulting from a unit current through line DE.

Table IV shows the computation of loop flows for a unit current supplied to the network at any bus and withdrawn at E. It may be noted from Figure 2 that all of the junction points (busses) in the network may be "scanned" by a single "track" starting at point A and proceeding to point E, the slack-take-up bus, as follows: point A, line AB, point B, line BC, point C, line CD, point D, and line DE. Table IV shows the lines and busses arranged in order of this track. The entries in this table for each line are the loop flows resulting from a unit current flowing through the line. These may be computed, as discussed in the previous paragraph for lines DE and CD, by multiplying the line resistance by the inverted matrix terms summed for the loops containing the particular line. The bus entries in Table IV are formed by taking progressive totals of the line entries starting at the slack-take-up bus and working up the track toward bus A. The bus entries are the loop flows which would result from a unit current supplied at the bus and withdrawn at the slack-take-up bus.

Table IV also shows the loop currents for a unit voltage inserted at V. Since V is in line BC which is in loops 1, 2, and 3, then k_1 equals k_2 equals k_3 equals V, and the entries in Table IV are formed by adding all three rows of the inverted matrix.

Having the loop flows, the knowing that the lines in the track between any particular bus and the slack-take-up bus must carry unit current for unit load at that bus, the entries in a general flow solution may be formed by combining components. The portion of Table V labeled "case 1" is the general flow solution. The line AB entry for load at A, 0.276, is equal to 1.000 plus (-0.1724) plus (-0.5530) since this line is in the track between current entry point and slack-take-up bus and is in loops 1 and 3.

The portion of Table V labeled case 1 enables line flows for any set of current loads and voltage V to be readily obtained. Loads are positive when current enters the network and negative when current is withdrawn, and voltage V is positive when it tends to force current from C to B in line CB. The currrent in each line is equal to the sum of the products of loads A, B, C, and D and voltage V times the proper coefficients from Table V. Thus, assuming specific loads $A=1$, $B=-2$, $C=-3$, and $D=5$ and voltage $V=0.1$, the flow from A to B would equal $(1)(0.276)+(-2)(-0.542)+(-3)(0.003)+(5)(-0.230)+(0.1)(-0.780)$, or 0.123, where the multiplying coefficients are taken from Table V. Other flows for this assumed loading are given in the answer portion of Table V.

The portion of Table V labeled "case 2" illustrates how the general solution may be used when the value of a circuit constant is changed. It is assumed that the resistance of line AB is changed from 0.1 ohm to R_{AB} ohms. This situation is handled by an extra current supplied at the sending end of line AB and withdrawn at the receiving end, the extra current being of such a value that the resulting current times the original AB resistance is equal to the resulting current less the extra current, times the desired resistance. Since the effect of an extra current supplied at A and withdrawn at B is equal to the extra current times (coefficient A less coefficient B) for any line, a row of coefficients may be computed by subtracting the bus B coefficients from the bus A coefficients in the general solution, Case 1. For line AB, coefficient A less coefficient B equals $0.276-(-0.542)$, or 0.818, and

Table I. Line and Loop Data for D-C Problem

Line	Resistance	Loops

subtracting one to eliminate the extra current leaves -0.182, which is the entry for line AB in Case 2 in Table V. An equation may be set up involving the initial flow in line AB, the extra current, and the desired resistance from A to B, knowing that the initial resistance from A to B equals 0.1 ohm, as follows:

$$(F_{AB}+0.818EC)(0.1)=(F_{AB}-0.182EC)R_{AB}$$

where F_{AB} = initial flow from A to B, EC = extra current, and R_{AB} = new resistance from A to B. Solving for the extra current, EC, gives the multiplying factor listed for case 2 in Table V. Assuming the same loading and voltage V as for case 1, if resistance AB is changed from 0.1 ohm to 1.0 ohm, the extra current becomes 0.420 and the new current flow from A to B becomes $0.123+(0.420)\times(-0.182)$, or 0.047. Other flows for this condition are given in the answer portion of Table V.

R_{AB} could be infinite for line AB, an open circuit, and the multiplying factor would become $5.49F_{AB}$, which would give the proper currents throughout the network for this condition.

The portion of Table V labeled case 3 illustrates how the general solution may be used when a new circuit is added to the network. The new circuit to be added is the line from A to D, which is shown dotted in Figure 1. Assuming that unit current flows from A to D in the added leg, the effect on the network is the same as if a unit current were supplied at D and withdrawn at A, so that flow coefficients in Table V are formed by subtracting the bus A coefficients from the bus D coefficients. Thus the case 3 coefficient for line AB equals $-0.230+-0.276$, or -0.506. The actual flow in the added line from A to D will probably not be unity, but will be equal to the voltage around a loop divided by the resistance of the loop where the loop is formed by the added circuit and a path through the network, following the directional arrows, between the points of connection of the added circuit. The loop formed by the added leg consists of lines AD, DE, and EA, and the voltage around the loop equals $(-0.5)\times$ (flow DE) plus (-0.6)(flow EA) where the resistances of lines DE and EA are 0.5 and 0.6 ohms, respectively. The network resistance between points D and A is equal to the voltage drop between these points, due to a unit current supplied at D and withdrawn at A. From the known resistances of lines DE and EA and from the flow coefficients for Case 3 in Table V, the network resistance from D to A is equal to (0.5)(0.179) plus (0.6)(0.179), or 0.197 ohm. The current in the added circuit AD, which is the multiplier for case 3, equals

$$\left[\frac{-1}{R_{AD}+0.197}\right](0.5F_{DE}+0.6F_{EA})$$

Note that the new circuit added to the network could as well have been another network, and, having a general flow solution for each of the two networks, the flow coefficients and multiplying factor for interconnecting the two networks could be computed as discussed.

The changes in case 1 to produce case 2 and case 3 may be made simultaneously to produce case 4. Although the flow coefficients for case 4 are the same as those for case 2 and case 3 in Table V, the multiplying factors for this situation are mutually dependent and must be determined by solving two equations in two unknowns. If R_{AB} is assumed changed to 1.0 ohm, the multiplying factor for case 2 coefficients equals 3.412 (Flow $AB+\Delta AB$) where ΔAB is the change in flow AB, due to the case 3 change. Referring to Case 3 coefficients in Table V, it may be noted that ΔAB equals (-0.506)(case 3 multiplying factor). Similarly, if R_{AD} is assumed connected equal to 0.25 ohm, the multiplying factor for Case 3 may be expressed as equal to $(-2.237)(0.5DE+0.6EA+\Delta)$ where Δ equals $[(0.5)(-0.046)+(0.6)(-0.046)]$ (case 2 multiplying factor). Solving the equations for ΔAB and Δ simultaneously gives ΔAB equal to 0.534 and Δ equal to -0.114. The multiplying factors for case 2 and case 3 are then 2.242 and -1.055, respectively, assuming the same loads and voltage V as previously. Under this condition, the flow from A to B is $0.123+(2.242)(-0.182)+(-1.055)(-0.506)$, or 0.249. Other flows for this condition are given in the case 4 row of answers in Table V.

Figure 2. Coding for d-c problem

General Voltage Solution

Table VI is a general voltage solution to the circuit of Figure 1. The coefficients in this table may be multiplied by the same factors as for the general flow solution, and the products summed for each bus to give the bus voltage with respect to a ground or neutral voltage. The slack-take-up bus, E, is used as a reference, and the voltages at all other points are computed by summing the voltage drops in the track between E and each other bus, that is, voltage E is known, voltage D = voltage E plus drop DE, voltage C = voltage D plus drop CD. The voltage drop for each line is equal to the flow coefficient from Table V times the line resistance from Table I, so that the computation of the general voltage solution consists of multiplying all of the flow coefficients by line resistances and sum-

ming the products down the track, row for row. In the case of the voltage V row, it is important to include voltage V in the drop in line CB when summing the voltage drops down the track. For the case 2 row, when computing the voltage drop in line AB, it is important to use the original R_{AB}, or 0.1 ohm, and to increase the flow coefficient by unity, so that the voltage drop equals $(0.1)(1.000-0.182)$, or 0.0818 volts.

The reciprocal theorem is illustrated by the fact that the voltage coefficients for busses A, B, C, and D form a symmetrical array in Table VI.

The general voltage solution forms a convenient basis for computing the resistance between any two network points. For example, the resistance from A to D, which was previously computed to be 0.197 ohm, may be computed from the coefficients in Table VI for busses A and D for loads at A and D. Since the resistance from A to D equals voltage A minus voltage D, with a unit current supplied at A and withdrawn at D, the resistance equals $0.331-0.224-0.224+0.314$, or 0.197 ohm. Because of the symmetry of the voltage coefficients, the resistance may also be expressed $0.331+0.314-2\times(0.224)$, or 0.197 ohm.

Other General Solutions

A general flow and voltage solution may be prepared for a series voltage inserted in each line of the network. The computation of this solution is the same as the computation of the voltage V row in the previous example. Although this general solution has little significance in the d-c problem, it is useful in carrying out the steps in successive approximations in a-c networks. Note that, for the case of the series voltage, a unit drop, in addition to the resistance drop, for the particular line containing the series voltage, must be considered when computing the general voltage solution.

Another general solution which is frequently of use consists of a set of coefficients for each loop in the network, so that a constant may be inserted in any loop and all flows and voltages determined by multiplying the constant by the coefficients. The voltage would be in error for this solution unless the constant drop were located at a particular point, so that it could be added to all voltages in the track beyond that point.

Application to A-C Power Circuits

The d-c general solution for flows and voltages, which was based upon exact application of Kirchhoff's laws, may be extended to a-c networks by suitable approximations, and, if properly applied, will solve load-flow problems with great accuracy and speed. If, in the d-c problem, the resistances were replaced by reactances, current flows and loads by power flows and loads, and voltage V by a phase shifter with V radians of phase shift, the general flow solution would give, for an a-c circuit, the power flows for a given set of loads based upon the making of PX plus phase shift zero about each loop. The d-c general voltage solution would become, for the a-c case, a general solution for phase angles at each bus expressed in radians and based upon a known angle at the slack-take-up bus. Similarly, substituting reactive power for current in the d-c case, and transformer boost or buck for voltage V, would result in a general solution for reactive power flows and bus voltages based upon a known voltage at the slack-take-up bus.

Answers obtained from application of the general solution as discussed in the foregoing paragraph would be in error, due to the assumption of zero loss of power and reactive power and due to the assumption of phase shift equal to PX and voltage drop equal to QX. From the vector diagram shown in Figure 3, it may be noted that the IZ voltage and phase angle drops may be expressed respectively:

$$(E+PR/E+QX/E)\sec\theta-E \text{ and } \tan^{-1}(PX-QR)/(E^2+PR+QX)$$

The errors from the assumption of zero loss, and from rough approximation of voltage and phase angle drops, may be reduced by reapplying the answers to the general solution in a method of successive approximation.

Losses may be taken into account by computing the loss for each line from the approximate flow and voltage and then considering the loss as an additional load at the sending end bus, if receiving flows are desired. Sending and receiving ends of lines are based on the directional arrows in the initial coding rather than the actual direction of flow.

The difference between the phase angle drop and voltage drop based upon PX and QX, respectively, and the more accurate phase angle drop and voltage drop based upon the approximate flows and exact equations from the vector diagram in Figure 3, may be computed for each line by subtracting PX or QX, as the case may be, from the drop computed from the accurate equations. The difference thus obtained may be regarded as a series voltage or phase angle for each line, which may be multiplied by the coefficients in a general solution, computed for a series voltage in each line to obtain corrective terms to be added to original flows and voltages to obtain improved answers.

It is necessary to work in the per unit system so that voltages will be near unity, and angles should be in radians so that the difference between an angle and its tangent will be small. Charging current is considered as additional reactive load at

the busses by using nominal *pi* representation for all lines.

General Solution Including Reactance and Resistance

Although the general solution based upon reactances only is a useful tool in network analysis, and can lead to exact answers by successive approximations, it is believed that a more elaborate general solution by which power, reactive power, resistance, and reactance are balanced simultaneously will prove to be more practical.

The expedient of balancing power and reactive power separately and alternately in a scheme of successive approximations was devised to avoid simultaneous equations in complex numbers, or to avoid having twice as many equations in twice as many unknowns. Since the general solution method involves simultaneous equations only in the initial computation of the coefficients, the economy of halving the number of equations at the expense of increasing the subsequent work to obtain answers becomes questionable. In many cases the accuracy of answers obtained from a single approximation using the general solution in resistance and reactance will be adequate.

Figure 4 is the impedance diagram of the high-voltage network of a utility company, Figure 5 shows the coding for this circuit, and Table VII gives the lines, resistances, reactances, and loops. Table VIII shows the form of equations to make the summation of $(PX-QR)$ and $(QX+PR)$ zero about loops simultaneously. In Table VIII, k_1, k_2, and k_3 represent phase angles not due to loop flows in loops 1, 2, and 3, respectively, and k_4, k_5, and k_6 represent voltages not due to loop flows in loops 1, 2, and 3, respectively. P_1 represents power circulating in loop 1 and Q_1 represents reactive power circulating in loop 1. The coefficients of the P and Q variables in the equations of Table VIII lack symmetry, due to the difference in signs of the resistance terms in the phase angle equations from those in the voltage equations. However, the coefficients in Table VIII may be divided by the dotted lines into four smaller sets, each of which is symmetrical.

Table IX shows the numerical values of coefficients in Table VIII, formed by summing the resistances and reactances from Table VII by loops, some numerical values arising in the matrix inversion (explained in the Appendix) and the inverted matrix. The inverted matrix is similar to the equation coefficients in that it lacks symmetry only by signs, and in that it may be divided into four smaller matrices, each of which is symmetrical. Although the network contains four loops, loop 4 does not mesh with loops 1, 2, and 3 and may be treated separately to avoid groups of zeros in a larger matrix. Table IX also shows the equation coefficients for loop 4 and the inverted matrix.

Having the inverted matrix, the loop flows for a unit load at each bus may be determined in a manner similar to the method used in the d-c example, busses and lines are arranged in tracks, line impedances are multiplied by inverted matrix terms, and bus terms are formed by taking progressive totals of the products. In the sample problem, bus F is the slack-take-up bus and all other busses may be scanned by two tracks: (1) A, AB, B, BC, C, CD, D, DE, E, EC, CF, and F; and (2) G, GH, H, HI, I, IJ, J, JF, and F. Table X lists the lines and busses in order of these two tracks. Consider a unit quantity of power entering the network, shown in Figure 5, at E and being withdrawn at F, the slack-take-up bus. This unit power may be assumed to flow through lines EC and CF, with the proper values of circulating power and reactive power to balance phase angles and voltages about the loops. This assumption of unit power flow through line EC, which is in loops 1 and 2, makes, in the equations

i	0.287	0.442	−0.746				

Given: Aa, Ab, Ac, Ba, Bb, Bc, Ca, Cb, and Cc, where Ab = Ba, Ac = Ca, and so forth

Enter: Da = Eb = Fc = 1.0

Then: Da(Aa) = Ad; Da(Ba) = Bd; and Da(Ca) = Cd
−1/Ad = Gd
Gd(Bd) = Ed; Gd(Cd) = Fd
Eb(Bb) + Ed(Bd) = Be; Eb(Cb) + Ed(Cd) = Ce
−1/Be = Ge
Ge(Ce) = Fe
Fc(Ce) + Fd(Cd) + Fe(Ce) = Cf
−1/Cf = Gf

And: Gf = Ci
Ci(Fe) = Bi = Ch
Ci(Fd) + Bi(Ed) = Ai = Cg
Ge + Ch(Fe) = Bh
Ch(Fd) + Bh(Ed) = Ah = Bg
Gd + Cg(Fd) + Bg(Ed) = Ag

Check: Ag(Aa) + Bg(Ba) + Cg(Ca) = −1
Ag(Ab) + Bg(Bb) + Cg(Cb) = 0
Ag(Ac) + Bg(Bc) + Cg(Cc) = 0
Ah(Aa) + Bh(Ba) + Ch(Ca) = 0
Ah(Ab) + Bh(Bb) + Ch(Cb) = −1
Ah(Ac) + Bh(Bc) + Ch(Cc) = 0
Ai(Aa) + Bi(Ba) + Ci(Ca) = 0
Ai(Ab) + Bi(Bb) + Ci(Cb) = 0
Ai(Ac) + Bi(Bc) + Ci(Cc) = −1

Figure 3. Vector diagram

$$\text{Voltage drop} = \left(E + \frac{PR}{E} + \frac{QX}{E}\right) \sec\theta - E$$

$$\text{Phase angle drop} = \tan^{-1} \frac{PX - QR}{E^2 + PR + QX}$$

shown in Table VIII, $k_1 = k_3 =$ the reactance of line EC, because k_1, k_2, and k_3 are phase shifts which are assumed equal to PX, and P is unity. Similarly, $k_4 = k_5 =$ the resistance of line EC. Thus, the entries in Table X for line EC are in two rows, one the product of X times the sum of the inverted matrix rows for k_1 and k_2, and the other the product of R times the sum of the inverted matrix rows for k_4 and k_5. For line CF, which is in loops 1 and 3, $k_1 = k_2 =$ reactance of line CF, and $k_4 = k_5 =$ resistance of line CF, and the entries in Table X for line CF are formed by products of the resistance and reactance by the proper rows of the inverted matrix. The loop flows for the unit power load entering the network at E equal the sums of the loop flows for unit power flow through lines EC and CF. The entries for other lines and busses in Table X are formed similarly.

Owing to the symmetry of the inverted matrix, except for the reversed signs, Table X may also be used for unit reactive loads. For this case, the power and reactive power about loops must be interchanged, and the power terms have the reversed sign.

The loop flows from Table X may be combined with the unit flows to obtain the general flow solution shown in Table XI. This table shows that the P and Q coefficients for any line are the same for P and Q loads, respectively, at any bus, and that the coefficients are the same except differing in sign for Q and P loads, respectively, at any bus. Since, with F as the slack-take-up bus, the effect of the loop 4 portion of the network is independent of the loops 1, 2, and 3 portion, the general flow solution is divided into two separate parts in Table X, to avoid the large groups of zeros that would result if the two parts were assembled into a single solution.

It is assumed that the transformer, GH, is capable of changing in ratio and in phase shift. The last two rows in Table X, which come directly from the inverted matrix for loop 4, may be multiplied by the transformer ratio (per unit boost in a direction opposite the arrow in Figure 5) and phase shift, expressed in radians, to show the effects upon the flow of power and reactive power in all lines.

Table XII is a general voltage solution prepared from the power and reactive power flows in Table XI and the line data in Table VII, assuming voltage drop in each line to equal $PR + QX$. A similar table for phase angles at each bus, based upon an angle of $PX - QR$ for each line, may be prepared, but, owing to the symmetry of the flow coefficients in Table XI, the angle coefficients are similar to the voltage coefficients, and may be obtained from the voltage coefficients by first reversing the sign of the P voltage coefficient and then interchanging the P and Q voltage coefficients. Phase angle coefficients are given in Table XII for bus E to illustrate this relationship.

The general voltage solution tables are symmetrical, that is, the load on bus A affects the voltage and angle of bus D in the same manner as load on bus D affects the voltage and angle at bus A.

The general voltage solution for the loop 4 portion of the network shows the effect of transformer ratio and phase shift on the various bus voltages. The coefficients for the transformer ratio include a unit voltage drop in line GH as well as the $PR + QX$ drops, analogous to the unit drop in the voltage solution for the series voltage in the d-c problem.

Conclusion

The general solution affords a convenient basis for computing voltages and current flows in a d-c network, and is especially useful for determining the effects of changing the circuit or one of the circuit constants.

The exact solution developed for direct currents may be extended to a-c power networks by certain approximations, and general solutions for power flow, reactive power flow, voltage, and phase angle in terms of loads, transformer ratios, and phase shifts may be prepared. It is believed that system engineers will quickly become familiar with the use of the general solution as shown in Tables XI and XII whether or not they study the method of preparing the solution, and that system engineers, including those having ready access to a network analyzer, will find it desirable to have a general solution to their system computed. Fortunately the computation of the general solution for a power network is not a difficult job.

Although the general solution may be used for computing complete system studies from basic data to final answers refined to any desired accuracy and such

Figure 4. Circuit for a-c problem

Figure 5. Coding for a-c problem

computing may require less time than a network analyzer study if punched-card equipment is used, the general solution is most practical for investigating the effects of slight changes to an existing system study. The existing study may have been computed, prepared from the readings from substation meters, or read from a network analyzer. Some types of changes may be computed more rapidly than they may be adjusted and read with a network analyzer, even if the network is set up and balanced at the time. Answers to frequently arising questions, such as the effect of an increased load on a flow or voltage at some point in the system, may be obtained very quickly. Referring to the circuit of Figure 4 and the general voltage solution in Table XII, suppose that it is desired to determine the amount of reactive power required at bus G to raise that bus voltage by five per cent, holding the slack-take-up bus at constant voltage. The answer is 0.05/-.3305, or 0.15 per unit vars. If it is desired to determine what change in phase shift of phase shifter GH will reduce the power flow in line HI by 0.1 per unit watt, the answer, from Table XI, is 57.3(0.1)/-0.549, or about $10^1/_2$ degrees. The 57.3 converts the phase shift from radians to degrees.

The methods of using the general solution to determine the impedance between network points, the effect of a change in a circuit constant, or the effect of interconnecting two networks is not given in detail in this paper for the a-c problem, but, by analogy to the d-c cases, it is apparent that similar mathematics will handle the a-c case. If desired, the general solution may be modified to give results directly in kilovolts, kilowatts, kilovars, and degrees instead of in per unit volts, watts, and vars, and in radians.

Appendix. Method of Inverting Symmetrical Matrix

Table XIII shows a method of inverting a symmetrical matrix which is quite practical for network analysis work. The method is well adapted to desk calculators since most of the steps involve the sums of two-factor products, and the desk calculator may accumulate the sums while the multiplications are being performed. Although the inverted matrix by this method has all signs reversed from the inverted matrix in mathematics, the reversed signs are beneficial if the equations are set up equal to zero, that is, with the "k" terms to the left of the equals sign.

In Table XIII a numerical example is worked out, and all steps are given in sequence below the example. The original matrix consists of rows a, b, and c of columns A, B, and C, and the inverted matrix consists of rows g, h, and i of columns A, B, and C. The steps may be readily followed, as each element in the numerical example is positively identified by a capital letter indicating the column and a lower case letter indicating the row. It may be noted that the numerical example is from the equations shown in Table III for the d-c problem. The steps illustrated in Table XIII follow a logical pattern, and it is believed that the reader will have no difficulty in extending the method to any number of variables.

Table IX shows a numerical example of the inversion of a 6-way matrix of the type arising in a-c network analysis. This matrix lacks symmetry in that the signs of the upper right fourth are reversed from the signs of the lower left fourth. However, the method of inverting the symmetrical matrix, shown in Table XIII, will also work for the special non-symmetrical matrix of Table IX provided that, when the solution has progressed through the row above the dashed line, the signs of all terms within the parentheses are reversed. Also, the signs of the upper right fourth of the inverted matrix should be reversed from the signs of the lower left fourth. Less than half of this special type of inverted matrix must be computed and the remainder may be filled in by symmetry.

Discussion

Glenn W. Bills (Bonneville Power Administration, Portland, Ore.). Dunstan's paper is an excellent contribution to system engineering. It is pleasing to see that he stresses his method of analysis rather than the novel use of an International Business Machine-type accounting machine, and that he has streamlined and improved the network solution which was presented in his first paper.

One distinct advantage of the general solution method of power network analysis is that there is no limit to the size of the systems which can be studied. We have recently doubled the number of line, load, capacitor, and generator units in our a-c network analyzer and are preparing for our first load study on the enlarged analyzer. Despite the increase in the number of board units, every unit is to be used on our next study of the Northwest interconnected system, and we could use additional units.

If the initial computation of the general solution for our power systems in the Northwest is not too time consuming, it would be desirable to set it up on our IBM machine and have it available at all times. Frequently someone requests an immediate answer to a problem involving the addition of a transformer, load, or line somewhere in our system when our analyzer is employed on other problems. For such cases the general solution, if already computed, could give a quick and accurate answer and so be invaluable.

Wouldn't it be possible to adapt this method to the calculation of transient stability swing curves, as only the generator-phase angles are changed for each step in the procedure, and all system impedances and generator and synchronous condenser voltages are fixed?

In many of our analyzer studies we resort to the use of equivalent networks to simplify board setups. These equivalents are either computed longhand or measured on the analyzer; Dunstan's method should enable us to readily obtain such equivalents in less time and with greater ease than has been possible in the past.

For large power systems where there may be as many as fifty loops, we wonder if the preliminary work of coding might not present an extremely difficult task to the average system engineer, especially when there exist complicated networks. Also, the inverting of matrices is usually a tedious and difficult undertaking although the method shown by Dunstan appears to be simple and can be performed without a thorough knowledge of matrix theory.

Dunstan is to be commended for the completeness of the two illustrative problems in his paper. These problems should help an engineer who is employing the general solution of a power network for the first time.

J. B. Ward (Purdue University, Lafayette, Ind.). In application of the general solution method described in this paper to the analytical solution of a power-flow problem the generation and loads are treated as impressed currents. This approach, as an approximation to actual conditions in a power network, is frequently much more fruitful than the use of constant voltage sources and constant impedance loads. This same approach together with the application of the superposition principle has been used in the development of various forms of a loss formula in which the total system loss is expressed in terms of the loading of generators and tie lines,[1,3] and in other papers on analytical methods of network solution.[2-6]

Power stations, through the action of voltage regulators and governors, usually maintain bus voltage and power loading constant, that is, in terms of classical linear network analysis they combine certain features of both current and voltage sources. One result of this is that the relative angles between generator buses vary considerably with different operating conditions. This elusiveness of the bus angles greatly complicates analytical solution by any method and contributes to the necessity of using successive approximations.

The author mentions that the coefficients or distribution factors for unit load at each bus can be computed alternatively by star-delta transformation or simultaneous equations. The method employed in the paper for evaluating these distribution factors is basically a solution of simultaneous equations through inversion of the matrix of coefficients of the mesh voltage equations (Table II and Table VIII). A recent book by Richardson[8] describes a tabular solution of networks, based on the substitution method of solving simultaneous equations and adapted to slide rule or calculating machine use, which could be used for this purpose. The network calculator might also be used to obtain a set of such distribution factors.

The methods described in the paper for

modifying a known solution to determine the effect of network changes, such as line outages, impedance changes, tap changes, etc., are very useful for obtaining additional information without the necessity of carrying through a new complete solution for each change. The superposition principles involved are not limited to an analytical solution but might also be applied to extend the life and usefulness of network calculator studies. Procedures of a similar nature based on superposition have been described by other authors,[4-6] and the references given here may be of interest to those who wish to pursue the study of these methods further.

The present paper describes a well-organized and coordinated method of obtaining and modifying a network solution. However, it appears that one definite limitation is the use of a single slack-take-up bus. In many high-voltage transmission studies voltage is held at a specified value, within reactive generating capabilities, at all generating stations and at numerous synchronous condensers in substations. In effect, this means that with respect to reactive power flow many buses act simultaneously as slack buses. The reactive power division among sources can vary widely with different line arrangements, even though the power generation schedule remains the same. For example, a change in tap setting can shift reactive power between sources with the real power loading held constant. This feature of many power network problems introduces serious complications for any analytical solution and requires cut and try procedures in calculator studies. It seems quite possible that in a system of this type analyzed by the method of the paper, considerably more than the one or two successive approximations mentioned by the author might be required in order to obtain with sufficient accuracy the desired solution.

It appears to the writer that examples of power networks for which the method of this paper seems particularly well adapted are 4 kv or 120/208 volt networks. These networks can usually be treated as single-source systems, conforming to the use of a single slack bus. The presence of many small loads and the wide range in impedance values of feeders, banks, and loads impose serious limitations on the solution of these networks by present day a-c network calculators. The use of business machines could relieve the burden of handling large numbers of branches. A general solution of the type described would be very useful for providing information relative to the addition of new banks or vaults, reinforcing secondary mains, and studying effects of large blocks of new load on secondary and bank loadings.

Lyle A. Dunstan: The author is indebted to Bills and Ward for bringing forth ideas concerning the general solution for a power network.

Bills suggests the computation of a general solution for the Northwest interconnected system which might contain as many as fifty loops. The inversion of an n-way symmetrical matrix by the method given in the appendix involves n divisions and $1/2(n^2 - 1)(n + 2)$ multiplications. Thus if $n = 50$, 64,974 multiplications would be required, and if the solution were to be made to balance P and Q simultaneously, n would equal 100 and 509,949 multiplications would be required, a rather formidable task. However, the matrix would contain a large number of zeros since each loop would not mesh with each other loop. Further, it is probable that all 50 loops would not be interdependent so that the 50-way matrix would break down into several smaller matrices greatly simplifying the solution. For example, the a-c example in the paper, which was an actual power network, contained only four loops, but of these four, three were interdependent and one was independent of the other three.

The enlarged Bonneville Power Administration network analyzer contains 130 lines, 18 generators and 70 loads if data in the author's file are correct. If it is assumed that all of these analyzer units are connected into a circuit and that there is a bus for each generator and load, the number of loops in the network will equal one plus the excess of lines over busses or $1 + 130 - (70 + 18)$ or 43. Thus, a study of 50 loops is a large study in terms of the capability of modern large network analyzers.

Ward mentions that considerably more than two approximations might be required to obtain sufficient accuracy because of adjustments in reactive loading and transformer taps. It was not intended to imply in the paper that one or two approximations would settle reactive loading or transformer taps, but rather that, having the loading and transformer ratios, one or two approximations would give all network answers with sufficient accuracy.

The author fails to understand Ward's comment that the use of a single slack-take-up bus in the computation of the general solution is a disadvantage, since power and reactive power may be varied at any bus in the network with equal facility. Perhaps the term "slack-take-up bus," which was a carry-over from a previous paper, causes difficulty. This bus should be more properly referred to as "reference bus."

Ward's list of references should prove very helpful, especially the book by D. E. Richardson. Richardson, and William B. Roos, superintendent of the Laboratory Department of the Mexican Light and Power Company, Ltd., have called the author's attention to the fact that the inverse of the matrix of coefficients of the voltage drop equations corresponds to Richardson's "set of transfer conductances" (chapter VIII of his book).

A Practical Approach to Calculating Optimum Performance of Semiconductor Rectifiers

EARL D. WILSON
NONMEMBER AIEE

Synopsis: Applying Kirchoff's circuit laws to a conventional four-arm rectifier bridge, an expression is derived for efficiency in terms of R (effective reverse resistance of one arm), F (effective forward resistance of one arm), and L (ohmic load resistance). Knowing that R and F can be kept constant by separate adjustments of input voltage and temperature of the cells enables us to maximize efficiency, E, with respect to L. The optimum value of L turns out to be $\sqrt{RF}$, the geometrical mean of forward and reverse resistances. This value of L yields $E_{max} = [(q-1)/(q+1)]^2$, where $q = \sqrt{R/F}$. Further analysis shows that $\sqrt{R/F} = V_R/V_F$ for optimum L, where V_R and V_F are corresponding values of reverse and forward voltage drops, so that E_{max} is expressible in terms of V_R and V_F alone. Three families of curves are given to illustrate manipulation of the simple empirical data required, resulting in a final plot of E_{max} versus temperature for various current densities in the cells. An important feature of the process depends on the interesting analytical result that for maximum efficiency the reverse and forward losses are equal, making it possible to correlate values of V_R and V_F. Because the empirical data involved are strictly applicable only when R and F are not appreciably affected by previous values of V_F and V_R respectively, a modified technique is suggested in which data are observed only when optimum L is in the circuit. It is shown that under these conditions $E_{max} = (V_L/V)^2$ where V_L is the rms drop across L and V is the a-c input voltage. Interpretation of results is discussed.

WHEN a rectifier cell is functioning in a conventional circuit such as that diagrammed in Figure 1, it presents an effective resistance F to flow of current I_F in the forward direction and likewise an effective resistance R to flow of current R_R in the reverse direction. In the sketch, symbols are intended to illustrate conditions during a half cycle of input voltage V. Although F and R interchange each alternate half cycle, symmetry is preserved and analysis for any half cycle applies to continuous performance. For simplicity and clearness, analysis is confined to a single-phase circuit with a plain ohmic load resistance L. Furthermore, the rectifier elements will be considered on a unit area basis, effectively one cell per arm, each having one square inch of active area. Extension to multiple elements is straightforward.

Applying Kirchoff's current and voltage laws, the following basic equations are readily set up:

$$I = I_F + I_R \tag{1}$$

$$I_L = I_F - I_R \tag{2}$$

$$V = I_R R + I_F F \tag{3}$$

$$V = 2I_F F + I_L L \tag{4}$$

Figure 1. Diagram of conventional 4-arm rectifier bridge with symbols for effective reverse and forward resistances during a half cycle

where the only new symbols are I for the input current and I_L for the rms current through the load. From these equations it is not difficult to compute the rms wattage output as

$$W_o = \frac{(R-F)^2 L}{[(R+F)L+2RF]^2} \cdot V^2 \tag{5}$$

and the rms wattage input as

$$W_i = \frac{R+F+2L}{(R+F)L+2RF} \cdot V^2 \tag{6}$$

By definition, the efficiency of the rectifier is

$$E = \frac{W_o}{W_i} = \frac{(R-F)^2 L}{[(R+F)L+2RF][R+F+2L]} \tag{7}$$

Now R and F are not constant, being fundamentally individual functions both of applied voltage and temperature. Since L is a parameter independent of these two variables, it is possible to hold R and F fixed by adjusting input voltage and temperature while L is being changed. Hence it becomes permissible to maximize efficiency with respect to load resistance by differentiating E with respect to L and equating to zero. The optimum value of load resulting is

$$L_{opt} = \sqrt{RF} \tag{8}$$

In other words, the value of L to be used to get the highest E is simply the geometric mean of the effective reverse and forward resistances of the cell.

Substituting the optimum value of L into equation 7, the expression for maximum efficiency can be reduced to

$$E_{max} = \left(\frac{\sqrt{R/F}-1}{\sqrt{R/F}+1}\right)^2 = \left(\frac{q-1}{q+1}\right)^2 \tag{9}$$

where q is placed for $\sqrt{R/F}$.

For convenience in obtaining empirical data, it would be desirable to express

Paper 48-101, recommended by the AIEE electronic power converter committee; the electronics committee, and the metallic rectifiers subcommittee of the chemical, electrochemical and electrothermal committee and approved by the AIEE technical program committee for presentation at the AIEE Great Lakes District meeting, Des Moines, Iowa, April 1–3, 1948. Manuscript submitted November 12, 1947; made available for printing February 17, 1948.

Figure 2. Circuit diagrams showing how forward and reverse characteristics of rectifier cells may be measured

Figure 2A. How effective forward current-voltage characteristics of a 4-4-1 stack may be measured

Figure 2B. How effective reverse voltage-current characteristics of a 4-4-1 stack may be measured

Figure 3. Plot of empirical forward data for rectifier cells relating volts per cell to temperature at various current densities

E_{max} in terms of V_R and V_F, the reverse and forward voltage drops across the cell. Fortunately it can be shown by use of equations 2, 3, and 4 that, allowing $L=\sqrt{RF}$,

$$q=\sqrt{R/F}=\frac{V_R}{V_F} \tag{10}$$

Thus it appears that maximum efficiency can be expressed in terms solely of V_R and V_F.

Of practical interest in industrial design of rectifier units is the maximum efficiency which can be obtained at various current densities and temperatures. Our analysis indicates that we need only obtain data on values of V_R and V_F within a practical range of operating conditions. In Figure 2 are circuit diagrams illustrating how such measurements may be made. A 4-4-1 stack of cells (a four-arm bridge with four cells in series in each arm and one in parallel) is connected as shown in (*A*) for observations on forward voltage-current characteristics. The instruments measure rms values. A four-junction thermocouple (not shown) is employed to give mean stack temperatures. For elevated temperatures, radiant heat from a drying lamp aids in maintaining a desired level, while colder temperatures can be held by drawing vapor from dry ice through a small blower.

In Figure 2 (*B*) is shown a variation of the circuit to obtain similar data in the reverse direction.

Figure 3 shows a family of curves resulting from the forward data reduced to a unit area basis. Figure 4 gives the curves reduced from the reverse data. Technically these are all we need.

It becomes necessary now to point out that in the ratio q, the values of V_R and V_F must be corresponding values; that is, they must in each instance be the effective values of reverse and forward voltages which exist together in adjacent arms of the bridge for a given current density and temperature. How to select corresponding values is not obvious, but fortunately a pursuance of our mathematical analysis points the way.

Returning to equation 10, we can square both sides and rearrange the terms to obtain

$$\frac{V_R^2}{R}=\frac{V_F^2}{F} \tag{11}$$

This is a remarkable conclusion. The term on the left represents reverse losses in the cell, while the term on the right represents forward losses. Equation 11 states that for optimum load resistance ($L_{opt}=\sqrt{RF}$), reverse and forward losses are equal. In addition, this yields a straightforward means of matching V_R to V_F. Since $V_R^2/R \equiv V_R I_R$ and $V_F^2/F \equiv V_F I_F$, we need only plot $V_R I_R$ versus V_R and $V_F I_F$ versus V_F for a given temperature and pick off V_R and V_F for the same wattage. Figure 5 shows such a plot for a temperature of 50 degrees centigrade. Similar curves are drawn for the range of temperatures involved. Then by applying equation 9 to these data we arrive at a family of curves which may be plotted as shown in Figure 6. Here we have arbitrarily plotted E_{max} as a function of temperature for various values of rms current density in the forward direction.

A glance at Figure 6 reveals that there is a narrow temperature range and a narrow current-density range in which there is a highest maximum efficiency. Presumably the parameters associated with this area are what the designer seeks. Such parameters are available from reference to the system of data. For example, what is the optimum value of L associated with highest efficiency at the optimum temperature and optimum forward current density? By manipulation of equations 8, 9, and 10,

$$L_{opt}=\frac{V_F}{I_F}\left(\frac{1+\sqrt{E}}{1-\sqrt{E}}\right) \tag{12}$$

Substituting E and I_F from Figure 6 and the corresponding value of V_F from the curves in Figure 3 for the optimum temperature, the best value of L_{opt} is computed. Likewise, a little algebraic juggling yields for the optimum input voltage,

$$V=\frac{2V_F}{1-\sqrt{E}} \tag{13}$$

Again, if we are more concerned about this optimum rms current in the load, we can find:

$$I_L=\frac{2\sqrt{E}}{1+\sqrt{E}}\cdot\frac{I_F}{V_F} \tag{14}$$

A corresponding approximate d-c average current could be found by dividing the value by an empirical form factor, usually about 1.13.

It would not be fair to conclude the analysis of the circuit at this point without recognizing the following experimental limitations in obtaining the data:

1. I_R is neglected when I_F is measured.
2. V_F is neglected when V_R is measured.
3. V_F is measured only when V_R is small.
4. V_R is measured only when I_F is small.

These facts merit a brief consideration. A study of the two circuits sketched in Figure 2 will show that reverse currents in one set of arms are included in the observed forward currents, and also that the forward voltage drops in one arm caused by reverse currents in the other arm are included in the observed reverse voltages. However, in both cases the errors are second order, and (if the procedure were judged advisable) could be reduced to third order values by estimated corrections. The preceding items 3 and 4 cannot be so easily dismissed. Experience has revealed that the forward drop of a

Figure 4. Plot of empirical reverse data for rectifier cells relating volts per cell to temperature at various current densities

Figure 5. Plots of reverse and forward losses as functions of voltage at one temperature

Figure 6. Plot of maximum efficiency as a function of temperature for various rms current densities

cell may be affected by the application of normal reverse voltage in the previous half cycle. Again the reverse leakage may be affected by the value of forward current density in the previous half cycle. The degree of the effects varies greatly among various types of cells. In some, they are negligible; in others, they are so serious as to make the described method of obtaining data quite inapplicable. The analysis, however, is still correct.

In view of this operational variable, we wish to outline a modified experimental procedure which eliminates the uncertainty in the data.

From the circuit in Figure 1 it is apparent that

$$V_R - V_F = V_L$$

and

$$V_R + V_F = V$$

Hence

$$\frac{V_R}{V_F} = \frac{V + V_L}{V - V_L} \tag{15}$$

When this relation is substituted into equations 10 and 9, we obtain simply

$$E_{max} = \left(\frac{V_L}{V}\right)^2 \tag{16}$$

Here E_{max} is given in terms of the ratio of rms load voltage to rms input voltage. Of course, this is true only for $L = L_{opt}$. Equation 16 suggests a procedure for observing data under actual conditions of dynamic operation of the bridge. Let the unit be held at some fixed temperature in a conventional circuit such that the values of input voltage V and load resistance L can be arbitrarily and independently adjusted until the value of the ratio V_L/V as indicated by an rms ratio voltmeter reaches a maximum value. The square of this observed datum gives E_{max} for the given temperature. The process is repeated for other temperatures in the range of interest. The curve of E versus temperature will exhibit a maximum which is the absolute value of the highest E_{max} for the cells measured. Empirical optimum values of V, V_L, and L could be easily recorded to advantage during the experimental procedure.

Such data should be free from the objections inherent in those obtained by the former method and should be completely applicable to any type of commercial or developmental rectifier cell.

Discussion

Stephen J. Angello (Westinghouse Research Laboratories, East Pittsburgh, Pa.): Performance analysis of nonlinear devices is essentially a difficult problem.

Wilson has replaced the nonlinear rectifier problem by a linear one, and has thereby arrived at a very useful guide for practical measurements.

There are limitations to this method in addition to those mentioned by the author. The choice of a bridge circuit eliminates tedious matching of boundary conditions at the half-cycle points provided that the rectifiers in the bridge arms are alike, or at least pairwise alike.

The equations one to four imply that the rms values of the fundamentals of the nonsinusoidal wave forms are of major importance and harmonics are neglected. The "effective" R and F are the resistances presented to fundamental currents.

An attempt to extend the theory to higher harmonics would spoil the beautiful simplicity of the method.

E. D. Wilson: The concept of replacing the nonlinear rectifier by a linear one did not originate with the author, but was suggested in a paper by P. O. Huss.[1]

Analysis of Unsymmetrical Machines

KURT BURIAN
MEMBER AIEE

UNSYMMETRICAL 2-phase and single-phase induction machines, such as the capacitor and the split-phase motor with windings not in quadrature, can be analyzed by methods based either on the double-revolving field theory or on the cross-field theory of the single-phase motor. Whereas papers on the analysis of unsymmetrical machines based on the double-revolving field theory have been published,[1,2] no reference to an analysis based on the cross-field theory can be found. This is particularly regrettable in view of recent publications[3,4] which show the usefulness of the cross-field theory for the design of permanent split-phase motors.

It is the purpose of this paper to analyze the unsymmetrical machine from the viewpoint of the cross-field theory, and to derive an equivalent circuit for the machine.

In the following analysis only fundamental fluxes will be taken into account, the air gap will be assumed uniform, and the rotor will be assumed to have a symmetrical polyphase circuit of either the cage or the wound type. These assumptions are commonly made in induction motor theory.

Figure 1. Unsymmetrical machine

Stator Magnetomotive Force

Let the auxiliary winding of the stator of an unsymmetrical machine be displaced from the main winding by α electrical radians, as shown diagrammatically in Figure 1. The magnetomotive force H set up by the two windings can then be expressed by

$$H = C[N_m I_m \sin x + N_s I_s \sin (x+\alpha)] \quad (1)$$

The reader is referred to the Table of Symbols for the meaning of the symbols in this and the following equations. Denoting the winding ratio N_s/N_m by a, equation 1 can be rewritten

$$H = CN_m(I_m + aI_s \cos \alpha) \sin x + CN_s I_s \sin \alpha \sin (x+90) \quad (2)$$

It is apparent from equation 2 that a magnetic field identical to that in the unsymmetrical machine exists in the air gap of a motor with the same main winding as that in the unsymmetrical machine, and with an auxiliary winding shifted relative to the main winding by 90 electrical radians provided that the current in the main winding equals

$$I_m' = I_m + aI_s \cos \alpha \quad (3)$$

and the current in the auxiliary winding equals

$$I_s' = I_s \sin \alpha \quad (4)$$

as shown diagrammatically in Figure 2.

Basic Equations of the Cross-Field Theory

The relations between the air-gap voltages and the rotor currents of a 2-phase or single-phase machine with windings in quadrature are well known. In the notation of this paper where these quantities are expressed in main-winding terms, the equations linking the components of the air gap voltage and the rotor currents in the x and y direction are

$$Z_s I_x = E_x - jSE_y - SX_s I_y \quad (5)$$

$$Z_s I_y = E_y + jSE_x + SX_s I_x \quad (6)$$

Furthermore, the components of the air gap voltage in any direction can be expressed by the product of the magnetizing impedance and the components of all the currents in that direction.

Thus, the components of the air gap voltage are

$$E_x = Z_m \sum_n I_{xn} \quad (7)$$

$$E_y = Z_m \sum_n I_{yn} \quad (8)$$

Finally, the voltage applied to any winding must be balanced by the sum of all induced voltages in the winding and the voltage drop due to the local impedance of the winding. This can be expressed generally by

$$V = \sum_n (E_n) + ZI \quad (9)$$

Equations 5 to 9 are the well-known relations derived from an analysis based on the cross-field theory.

Basic Equations of the Unsymmetrical Machine

Equations 5 to 9 can be readily applied to the motor of Figure 2:

$$Z_s I_x = E_x - jSE_y - SX_s I_y \quad (10)$$

$$Z_s I_y = E_y + jSE_x + SX_s I_x \quad (11)$$

$$E_x = Z_m(aI_s' - I_x) \quad (12)$$

$$E_y = Z_m(I_m' - I_y) \quad (13)$$

It should be noted that the auxiliary current I_s' in equation 12 was multiplied with a to reduce it to main winding terms.

Paper 48-105, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE Great Lakes District meeting, Des Moines, Iowa, April 1-3, 1948. Manuscript submitted February 2, 1948; made available for printing February 20, 1948.

KURT BURIAN is in the engineering department of G-M Laboratories, Chicago, Ill.

Figure 2. Equivalent machine with windings in quadrature

since all the other quantities involved are also in main-winding terms.

Applying equation 10 to both the main and auxiliary winding it follows that

$$V_m = Z_{1m} I_m + E_y \doteq j\omega M I_s \tag{14}$$

$$V_s = Z_{1s} I_s + E_s' \doteq j\omega M I_m \tag{15}$$

The term $j\omega M I_m$ was added to equation 15 to account for the voltage induced in the auxiliary winding by the local mutual leakage flux which links both the main and auxiliary winding of the unsymmetrical machine, but which does not cross the air gap. For the same reason the term $j\omega M I_s$ was added to equation 14. It should be noted that the local impedances Z_{1m} and Z_{1s} are defined here to include any circuit element used externally in series with the winding.

The air gap voltage E_s' can be found by taking the components of the voltages E_x and E_y in the direction of the auxiliary winding:

$$E_s' = aE_y \cos\alpha + aE_x \sin\alpha \tag{16}$$

where the factor a was used to reduce the voltages to auxiliary winding terms.

Substituting equations 3, 4, and 16 into equations 10 to 15, the following set of six equations results:

$$V_m = Z_{1m} I_m + E_y \doteq j\omega M I_s \tag{17}$$

$$V_s = Z_{1s} I_s + aE_y \cos\alpha + aE_x \sin\alpha \doteq j\omega M I_m \tag{18}$$

$$E_y = Z_m (aI_s \sin\alpha - I_y) \tag{19}$$

$$E_y = Z_m (I_m + aI_s \cos\alpha - I_y) \tag{20}$$

$$Z_s I_x = E_x - jSE_y - SX_s I_y \tag{21}$$

$$Z_s I_y = E_y + jSE_x + SX_s I_x \tag{22}$$

These six equations can be solved for the unknown currents I_m, I_s, I_x, and I_y and for the air gap voltages E_x and E_y. These quantities determine uniquely the performance of the unsymmetrical machine.

Torque Equation

Torque in an induction machine results from the interaction of the rotor currents with the air gap flux. Since the rotor currents and the air gap flux are the same for the motor of Figure 2 as they are for the unsymmetrical machine, and since the torque of the motor of Figure 2 is well known, the torque for the unsymmetrical machine follows immediately

$$T = |E_y|\,|I_x| \sin(E_y, I_x) + |E_x|\,|I_y| \sin(I_y, E_x) \tag{23}$$

It should be noted that the winding ratio does not appear in this equation, since by notation of this paper all quantities in this equation are in main winding terms.

Single-Phase Motor

For the case of a single-phase motor with windings not in quadrature, the voltages V_m and V_s are equal to the line voltage V. Furthermore, the coefficient of mutual inductance M is usually small, so that the terms involving M can be neglected. Under these conditions equations 17 and 18 reduce to

$$V = Z_{1m} I_m + E_y \tag{17a}$$

$$V = Z_{1s} I_s + aE_y \cos\alpha + aE_x \sin\alpha \tag{18a}$$

Figure 3. Equivalent circuit of the unsymmetrical machine

$V_1 = V/(a\cos\alpha)$	$I_1 = aI_s \cos\alpha$
$V_2 = V$	$I_3 = I_m + I_1$

$Z_6 = (Z_3' + R)\cot^2\alpha + R$	

Equivalent Circuit for the Single-Phase Motor

The set of six equations 17a to 22 can be used to design an equivalent circuit for the unsymmetrical machine. The solution of the problem of finding the equivalent circuit is not unique, and the circuit shown in Figure 3 is merely one of many possible solutions. Its preference over other circuits lies in that it reduces readily to known equivalent circuits for the limiting cases of $\alpha = 0$ and $\alpha = 90$ electrical radians.

The equivalence of the circuit of Figure 3 with the set of six equations is shown in Appendix III. For the limiting case of $\alpha = 0$ the circuit reduces to that of Figure 4 which is the equivalent circuit of a single-phase motor with two parallel windings. Except for the differences in notation, it is the equivalent circuit shown in reference 1.

For the case of $\alpha = 90$ electrical radians the circuit reduces to that of Figure 5 which again coincides with the equivalent circuit of reference 1.

Table I

Conclusions

Performance of the unsymmetrical induction machine can be predicted from design values of the motor by relations derived from the cross-field theory. The correctness of these relations is borne out by calculations on a sample motor the performance of which is given in references 1 and 2. Details of the calculations are given in Appendix II. The equivalent circuit developed from the basic equations lends itself to rapid solution by use of tabular methods such as are given in reference 5. Furthermore, the equivalent circuit can be simplified in particular cases by carefully chosen approximations.

Appendix I. Starting Conditions of Single-Phase Motor

For a single-phase motor at standstill ($S=0$), equations 17a to 22 can be readily solved for the unknown currents:

$$I_m = V(Z_{1s}+a^2Q-aQ\cos\alpha)/D \tag{24}$$

$$I_s = V(Z_{1m}+Q-aQ\cos\alpha)/D \tag{25}$$

where

$$Q = Z_3Z_m/(Z_3+Z_m) \tag{26}$$

$$D = (Z_{1m}+Q)(Z_{1s}+a^2Q)-a^2Q^2\cos^2\alpha \tag{27}$$

With the currents I_m and I_s known, the starting torque can be found from

$$T = 2aR_3|P|^2|I_m|\ |I_s|\sin\alpha\sin\varphi \tag{28}$$

where

$$P = Z_m/(Z_3+Z_m) \tag{29}$$

and φ is the angle between the vectors I_m and I_s.

Appendix II. Numerical Example

To illustrate the application of the equations given in Appendix I an example of a motor for which constants are given in references 1 and 2, is worked out here. Expressed in the notation of this paper the design constants of the motor are

$$Z_{1m} = 2.02+j2.79$$

$$Z_{1s} = (1.18)^2\times 5.12+3.0+j(1.18)^2\times 2.31-j14.5 = 10.13-j11.28$$

$$Z_3 = 2\times 2.06+j2\times 1.06 = 4.12+j2.12$$

$$Z_m = 2\times j33.4 = j66.8$$

$$a = 1.18$$

$$V = 110$$

From the manner in which the rotor and magnetizing impedances are defined here, these values are twice the corresponding impedances in reference 1. Using equations 24, 25, and 28, values for the currents and torque at various angles α are obtained. These values are contrasted in Table I with the values given in references 1 and 2.

Appendix III. Equivalent Circuit

To show the equivalence of the circuit of Figure 3 with the set of six equations 17a to 22, it is convenient to rearrange equations 21 and 22 as follows:

$$E_x = (Z_3'+R)I_x+jRI_y \tag{21a}$$

$$E_y = (Z_3'+R)I_y-jRI_x \tag{22a}$$

where

$$Z_3' = R_3/(1+S)+jX_3 \tag{30}$$

$$R = SR_3/(1-S^2) \tag{31}$$

Checking first the induced voltages it follows from Figure 3 that

$$E_1 = Z_5(I_1-I_5)$$

Substituting the values from Figure 3 it follows that

$$E_x\tan\alpha = Z_m\tan^2\alpha(aI_s\cos\alpha-I_x\cot\alpha)$$
$$E_x = Z_m(aI_s\sin\alpha-I_x)$$

which is identical to equation 19. Similarly it follows from Figure 3

$$E_3 = Z_mI(_3-I_4)$$
$$E_y = Z_m(I_m+aI_s\cos\alpha-I_y)$$

which is identical to equation 20. Furthermore

$$E_3 = Z_m(I_3-I_4)$$
$$jE_x = Z_m(jaI_s\sin\alpha-jI_x)$$

which again reduces to equation 19, and finally

$$E_4 = Z_7(I_7-I_4)$$
$$jE_y\cot\alpha = Z_m\cot^2\alpha(jI_m\tan\alpha+jaI_s\sin\alpha-jI_y\tan\alpha)$$
$$E_y = Z_m(I_m+aI_s\cos\alpha-I_y)$$

which again is identical to equation 20.

Applying Kirchhoff's law to the outer contour of meshes one and two, it follows that

$$V_1 = Z_1I_1+E_1+E_2$$

$$V/a\cos\alpha = aI_s\cos\alpha Z_{1s}/(a^2\cos^2\alpha)+E_x\tan\alpha+E_y$$
$$V = I_sZ_{1s}+aE_x\sin\alpha+aE_y\cos\alpha$$

which is identical to equation 18a. For mesh two it follows that

$$V_2 = Z_{1m}(I_2-I_1)+E_2$$
$$V = Z_{1m}I_m+E_y$$

which is identical to equation 17a. For mesh three it follows that

$$E_1 = I_5(Z_5-Z_3)+I_3Z_3$$
$$E_x\tan\alpha = I_x\cot\alpha(Z_3'+R)\tan^2\alpha+jRI_y\tan\alpha$$

which readily reduces to equation 21a. For mesh four it follows that

$$E_3 = I_4(Z_4+Z_3)-I_3Z_3$$
$$E_y = I_y(Z_3'+R)-jRI_x$$

which is identical to equation 22a. For mesh five it follows that

$$E_4 = I_5(Z_5-Z_3)+I_3Z_3$$
$$jE_y\cot\alpha = jI_y\tan\alpha(Z_3'+R)\cot^2\alpha+I_xR\cot\alpha$$

which again reduces to equation 22a. For mesh six it follows that

$$E_3 = I_6(Z_4+Z_3)-I_4Z_3$$
$$jE_x = jI_x(Z_3'+R)-RI_y$$

which again reduces to equation 21a. For mesh seven it follows that

$$V_3 = Z_8(I_7-I_6)+E_4$$
$$jV\cot\alpha = Z_{1m}\cot^2\alpha jI_m\tan\alpha+jE_y\cot\alpha$$

which reduces to equation 17a. And finally for the outer contour of meshes seven and eight it follows that

$$V_4 = I_8Z_{10}+E_3+E_4$$
$$jV/a\sin\alpha = jaI_s\sin\alpha Z_{1s}/(a^2\sin^2\alpha)+jE_x+jE_y\cot\alpha$$

which readily reduces to equation 18a.

Table of Symbols

$a = N_s/N_m$ winding ratio
E_x = air gap voltage in x direction, in main winding terms, in volts
E_y = air gap voltage in y direction, in main winding terms in volts
H = magnetomotive force
I_m = current in main winding, in amperes
I_s = current in auxiliary winding, in ampere s

Figure 4. Equivalent circuit for $\alpha=0$

$V_1 = V/a$ $\quad E_2 = E_y$ $\quad I_1 = aI_s$ $\quad I_4 = I_y$
$V_3 = V$ $\quad E_3 = jE_x$ $\quad I_3 = I_m+I_1$ $\quad I_6 = jI_x$
$Z_1 = Z_{1s}/a^2$ $\quad Z_4 = Z_3'$ $\quad Z_5 = R$

Oscillographic Study of Synchronous Motor Hunting

E. B. KURTZ
FELLOW AIEE

ALL synchronous machines are subject to hunting. When a synchronous motor operates under constant load and excitation, there is a definite phase angle between the impressed and the excitation voltage. If the load is increased the motor will momentarily be developing less power than is required by the load and it will begin to slow down to assume the phase position corresponding to the increased load. However, the motor cannot immediately take up the new phase position corresponding to the increased load because the inertia of the rotor will cause it to overrun this position. It will then be developing more power than is required and cause the rotor to speed up and overrun the new phase position in the other direction. The rotor will continue this hunting action until the oscillations are damped out by the damper-winding action. A similar sequence of oscillations takes place when load is suddenly removed.

When the motor hunts it causes all the electrical quantities to vary; the phase angle between the impressed and the excitation voltages changes and causes the line current to change; the power taken by the motor varies as the rotating parts give up and absorb kinetic energy; and voltages are induced in the field windings when there is relative motion between the rotating field and the field structure. The exact variation of these quantities is important but difficult to predict analytically. Hence, this paper which presents an oscillographic study of a synchronous motor subjected to sudden load changes.

Apparatus and Connections

The apparatus used in this investigation is shown in Figure 1 and the connection diagram is given in Figure 2. As shown, the laboratory setup comprises a synchronous motor, a d-c generator, a power-angle indicator, and a 6-element oscillograph for recording the transient electrical quantities.

The motor is rated 3-phase 5-kva 220-volts 60-cycles 6-pole 1,200-rpm. It was designed for laboratory use, and hence is probably rated lower than a commercial machine of the same size. Its rotor was equipped with a squirrel cage winding. Its windings were Y-connected and had a neutral lead which was used in measuring and photographing the electrical phase quantities.

The load was applied or removed by closing or opening the resistance-load switch, S, of the directly coupled d-c shunt generator.

The power angle indicator, Figure 3, consists of two parts; one a disk mounted on the synchronous motor shaft, and the other, a brush arm fastened to the shaft of a small auxiliary synchronous motor having the same synchronous speed as the main motor. On the periphery of the disk is mounted an insulated high resistance wire through which a constant direct current is caused to flow. This current is supplied through slip rings from a battery. The brush arm is of such length that it rides freely on the high resistance wire. When load is applied to the main motor, the main motor will fall behind the idly running auxiliary motor and the brush will move around on the wire a small distance. If the motors are initially brought into step in the correct position, the voltage drop between the brush and the voltage drop lead will be proportional to the power angle. After the two motors are in correct relative positions, the voltage drop thus becomes a direct and instan-

taneous measure of the angle. Connections to an oscillograph makes possible a linear record of the angle. A direct indication for steady values of power angle can be obtained by means of a low-reading voltmeter.

The oscillograph galvanometers were arranged as shown in Figure 2 to record:

Motor voltage (phase)–V_m
Motor current (phase)–i_m
Motor power (phase)–w_m
Motor field current–i_f
Load current (d-c)–i_L
Power angle–α_m

Steady-State Values

A set of seven oscillograms for the application of load, and six for the removal of load were taken with the motor field current as the independent variable. The values of the steady-state motor phase current, phase power, phase power factor, and the load current of the generator, corresponding to the values of motor field currents used are tabulated in Table I. In Figure 4 these steady-state values of motor phase current and power factor are plotted against corresponding values of field current, giving the well known synchronous motor V-curves. The magnitude of load on all oscillograms was kept constant at approximately 150 per cent of rated load. The field current corresponding to minimum line current and maximum power factor for this load is seen to be 3.9 amperes.

Application of Load

Oscillograms

The sudden application of load is more critical than the sudden removal of load because the motor is more liable to fall out of step when load is suddenly applied. Whether the motor will fall out of step depends upon the magnitude of the load applied, the moment of inertia of the rotating parts, the effectiveness of the damper windings, and the value of field current. After the motor has been built the only remaining variable for a fixed load is the field current. In this study 150 per cent full load was suddenly applied with values of field current ranging from 2.57 to 6.10 amperes. Figures 5 to 11, inclusive, show the oscillograms for the application of load arranged in order from the lowest to highest values of field current. Each oscillogram shows the exact variation of the synchronous motor's phase current, phase power, power angle, and field current, and the d-c generator's load current. The records are labeled to correspond to the galvanometer-element notation shown in Figure 2.

Table I

Motor Field Current, Amperes	Phase Line Current, Amperes	Phase Power, Watts	Phase Power Factor	Generator Load Current, Amperes
2.57	16.6	1,960	0.90 lag	20.0
3.00	15.6	1,840	0.93 lag	21.0
3.50	14.0	1,820	0.986 lag	21.0
3.90	14.2	1,820	1.00	20.4
4.50	14.4	1,810	0.951 lead	20.3
5.50	16.5	1,780	0.84 lead	20.4
6.10	18.2	1,760	0.72 lead	20.0

Having records of instantaneous phase voltage, phase current, and phase power, made it possible to obtain the record of phase power factor by calculation. This is the reason all electrical quantities in the motor were recorded as phase quantities. Power factor could also be obtained from the watt-galvanometer trace by taking the ratio of the average power to the maximum amplitude.

Power Angle Variations*

The oscillograms strikingly show how the rotor falls back when load is suddenly applied, how it forges ahead due to having fallen back too far, and how it then drops back again, only to surge forward once more. This oscillation about the new phase position naturally continues until it is damped out.

Table II gives the values of the power angle, taken from the seven oscillograms.

*The small high-frequency 20-cycle superimposed ripple is due either to a slight mechanical vibration or to hunting by the auxiliary motor.

for each thirty-three thousandth of a second during the first one and a half seconds after the load was suddenly applied. Figure 12 shows these values of the power angle plotted against time for five of the values of field current used. (Only five curves are plotted to avoid confusion on the graph.)

It is noted from Figure 12 that the amplitude of the first oscillation decreases as the field current is increased. This is still more evident in Figure 13 where this magnitude in degrees is plotted against field current. The field current produces the force which holds the synchronous motor in step. As the field current is increased the rotor becomes more tightly coupled, and hence is not as free to oscillate as widely.

Hunting Frequency

It is further noted from Figure 12 that the frequency of oscillation increases as the field current is increased. This is the inverse of the amplitude of oscillation. In Figure 14 the hunting frequency is plotted against field current. The frequency is seen to vary from one cycle per second to slightly over four cycles per second. The hunting frequency would appear to decrease to zero at about 2.1 amperes field current, with a corresponding increase in the magnitude of the first oscillation. The motor, of course, would be likely not to stay in step, for an oscillation of 80 degrees would undoubtedly exceed the limit of stability. Actually, the lowest value of field current with which the motor remained in step was

Figure 12 (left). Power angle variation during application of load plotted against time

Figure 15. Variations in power angle, power factor and field current during application of load plotted against time. Field current = 5.50 amperes

found to be about 2.50 amperes. This corresponds to an oscillation of approximately 65 degrees. It can thus be said that under-excitation produces a slow but wide-swinging rotor, while over-excitation produces a fast but narrow-swinging rotor.

Other Variations

Further examination of the oscillograms shows the current and power variations to be proportional to the power angle for all values of field current. This follows, since the power angle is the angle between impressed and excitation voltages. An increase in the angle increases the resultant voltage, which in turn increases the current. Except for variations in power factor, the power varies directly with the current.

Analysis of the oscillograms shows the power factor to follow the power angle variations. In Figure 15, calculated values of power factor are plotted along side the power angle variation for the case of 5.50 amperes field current. The two quantities are seen to be closely related.

The variations in the field current are related to the power angle variations, since they are caused by the relative motion of rotor and revolving flux fields. A change in power angle means a change in rotor position. When this change occurs, a voltage is induced in the field winding. The high inductance in this winding causes the current change to lag the induced voltage.

Removal of Load

Motor Versus Generator Action

When the load is suddenly removed, the motor draws more power from the line than is momentarily required, and will therefore be accelerated towards its no-

Figure 19 (left). Oscillogram of sudden removal of 150 per cent load with field current equal to 3.90 amperes

Figure 22. Oscillogram of sudden removal of load with largest value of field current of 6.10 amperes

load position. It cannot immediately take up the new angular position because the inertia of the rotor causes it to oscillate about the new phase position. If the entire load is removed and if the no-load power angle is small the oscillations will be likely to pass through the zero-angle position, in which case the motor will supply power to the line for short periods of time. The current will first decrease to a minimum at the zero-angle position and will then increase on the other side. This well-known phenomenon can be explained from the vector diagram shown in Figure 16, where

V = the applied voltage,
E_a = the excitation voltage,
E_e = the resultant voltage,
I_a = the current caused by E_e,
α_m = the power angle, and
$\theta = \text{Tan}^{-1} X_s/r_e$

As the motor hunts, the voltage E_a oscillates about the horizontal position thereby causing the resultant voltage E_e to vary in magnitude and phase position. When α_m is zero, E_e will be the algebraic difference between V and E_a. When α_m increases in either direction from the zero-angle position, E_e increases, and hence I_a increases. Therefore I_a has its minimum value at the zero power-angle position. When α_m is positive, the current is more than 90 degrees out of phase with E_a and hence represents motor action. The power thus changes from motor to generator power or vice versa when α_m passes through zero.

Oscillograms

Figures 17 to 22 inclusive are the oscillograms for the sudden removal of load arranged from the lowest to the highest values of field current. These oscillograms show a sudden decrease in current and power immediately after the load is dropped. At this time the rotor surges forward, due to excess power, to the zero power-angle position. The rotor, however, does not stop there, but on account of rotor inertia moves beyond the zero power angle position causing the machine to enter the generator zone on the vector diagram of Figure 16 (region of $-\alpha$). These transitions from motor to generator action or vice versa always occur at the points of zero power-angle. In fact, the zero-angle position can always be located on the oscillograms by erecting a perpendicular at the point corresponding to minimum line current, or of zero average power. By laying a straight edge across the oscillogram, it will be noted that perfect correspondence exists between these three zero values.

Hunting Frequency

The frequency of hunting during removal of load is plotted against field current in Figure 23. From the figure it can be seen that the frequency of hunting does not vary as widely during the removal of load as during application of load. The range covered is only 3 cycles per second to approximately $4^1/_2$ cycles per second. During application of load the range was

Figure 23 (left). Hunting frequency during removal of load plotted against field current

Figure 24. Power angle, power factor and field current variations during removal of load plotted against time (Field current = 2.57 amperes)

from 1 to 4 cycles per second. When the load has been removed the hunting represents more nearly the natural frequency of the rotating mass.

The damping action is also much less evident during removal of load. In Figure 22 for example, with 6.10 amperes field current the damping action is barely noticeable.

Similarly in Figure 11 prior to application of load, the motor was initially hunting even though it had been given several minutes to settle down.

Field Current Variation

During removal of load the field current becomes quite irregular as the rotor hunts through the zero angle position. At this point the direction of the induced electromotive force in the field circuit reverses. The current variation, of course, lags behind the voltage variation due to the inductance of the field circuit. The points of zero angle on the oscillograms therefore do not correspond to the points of maximum change in the field current.

During the application of load the power-angle oscillations were at all times on one side of the zero angle position and the induced voltage in the field circuit depended in magnitude and direction only on the instantaneous velocity of the field structure relative to the revolving field. The induced voltage changed direction only when the direction of motion changed. In the case of the removal of load, however, the induced voltage changes direction when the relative motion changes direction as well as when the rotor oscillates through the zero-angle position. The effect of the latter can be plainly seen on the oscillograms whenever the power angle crosses the zero angle line. An enlarged trace of these variations is shown in Figure 24 for removal of load with a field current of 2.57 amperes.

The power factor is seen to vary from 0 to 90 per cent as the motor hunts. It will also be noted that the power factor reverses polarity when the power angle passes through zero.

Experimental Determination of the Capacitance of Heavy-Current Busses Comprised of Solid or Tubular Rectangular Conductors

ROBERT D. TEASDALE
ASSOCIATE AIEE

THOMAS JAMES HIGGINS
MEMBER AIEE

IN an investigation of circuit transient recovery voltage Adams, Skeats, Van Sickle, and Sillers[1] outline a procedure for determining sizes of the relaying equipment necessary for the protection of central station power systems (or other heavy current systems) under fault conditions. The first step in this procedure is to obtain the equivalent circuit of the system to be relayed. In turn, this step requires determination of the equivalent circuits of both the electrical apparatus and the busses comprising the system.

In general, no difficulty attends obtaining the equivalent circuits of the electric apparatus. Equations and data sufficient for calculations are to be found in textbooks, handbooks, and manufacturer's catalogs. Again, no difficulty attends obtaining the resistive and inductive impedances of the equivalent circuits of the busses. Long established and well verified equations and curves are available in other literature.[2]

Calculation of the capacitive impedances is quite a different matter. The present literature does not encompass equations from which can be calculated the capacitances (and thus the capacitive impedances) of one of the major single and 3-phase bus designs, which is rectangular strap conductors isolated in concrete cells. The basic configuration of such an arrangement, Figure 1, a rectangular conductor at line potential isolated in a rectangular concrete cell (of sides c and d) at zero reference potential. In fact, of most of the heavy busses used in practice, equations for the capacitance are not to be found, for the mathematical analysis required to effect these equations has proved intractable.

As stressed in the previously mentioned paper[1] it is most important that the designer be able to calculate accurately the required capacitances.

"Calculation of the transient recovery characteristics involves the determination of the natural frequencies...from the inductance and capacitances of the circuit";... "the capacitive coupling of adjacent circuits...must be taken into account"; "[it] is extremely important that the capacitances of the higher frequency circuits be estimated accurately".

The method commonly employed to obtain the required capacitances is that utilized by the authors of the above paper[1] in the use of a free-hand graphical plot of the electrostatic field of the bus and approximate calculation of the capacitance therefrom.[3] However, other than purely nominal values can thus be obtained only by one skilled in such plotting, and even a skilled plotter requires appreciable time if any considerable accuracy is to be obtained, especially if a number of plottings is necessitated by an extensive system.

The available alternative methods for obtaining the field accurately have obvious disadvantages; numerically, by use of one of several finite difference procedures;[4] graphically, by use of exact drafting procedures;[4,5] or experimentally, by use of an electrolytic tank[6,7] or conducting plate.[7,8] The first requires very heavy computation; the second lengthy and tedious drafting; the third special apparatus. They are time consuming and are indirect methods (for the capacitance must yet be calculated from the field plot). In all, the accuracy with which the capacitance is obtained hinges on the fineness of the field plot and the subsequent interpretation and averaging of the

Paper 48-111, recommended by the AIEE basic sciences committee and approved by the AIEE technical program committee for presentation at the AIEE Great Lakes District meeting, Des Moines, Iowa, April 1–3, 1948. Manuscript submitted November 28, 1947; made available for printing February 11, 1948.

ROBERT D. TEASDALE is a graduate student and Gerard Swope Fellow in the department of electrical engineering with the Illinois Institute of Technology, Chicago, Ill., and THOMAS JAMES HIGGINS is a professor of electrical engineering, with the University of Wisconsin, Madison, Wis.

The authors are indebted to Doctor George Polya for providing us with equation 11 and to Donald Simmons for directing our attention to references 5, 6, and 8.

This paper is based upon a thesis supervised by Thomas James Higgins and submitted by Robert D. Teasdale to the faculty of the Illinois Institute of Technology in June, 1947, in partial fulfillment of the requirements for the degree of master of science in electrical engineering.

curvilinear mesh marked out by the mutually orthogonal flux and equipotential lines. Accordingly, regardless of the method chosen accurate calculation of the capacitance is an involved and lengthy process.

In consequence of these disadvantages, it is evident that it is most desirable to have a simple direct method which both quickly yields the capacitance of a bus of arbitrary geometry and lends itself to the rapid preparation of curves or equations for the capacitance of those configurations commonly encountered in practice. Such a method is available, but it would appear that this method is not widely known and has had very limited use. It is not mentioned in textbooks or handbooks. An exhaustive search of the literature has revealed only one published application, namely, for determination of the capacitances of a multiphase cable.[6,8]

Fundamental Theory

If the plates of a cylindrical capacitor of capacitance C and permittivity ϵ are considered as electrodes with the space between them filled with a conducting medium of resistivity ρ, it follows from well-known theory[9] that in rationalized units the resistance R between the electrodes is related to the corresponding capacitance through the equation

$$C = \epsilon\rho/R = \epsilon_o\epsilon_r\rho/R \qquad (1)$$

wherein the permittivity ϵ is the product of the absolute permittivity ϵ_o and the relative permittivity ϵ_r (≡dielectric constant K).

This equation suggests that the capacitance of a cylindrical capacitor can be determined by constructing metal electrodes of the same shapes as the plates of the capacitor, filling the space between these electrodes with a suitable liquid conducting medium of known resistivity ρ, measuring the resistance R with a Wheatstone bridge, and calculating C from equation 1.

Though this equation has long appeared in books on electromagnetic theory, and though, as is confirmed by the experimental work discussed below, the method is most feasible, it seems that the experimental method is not well known. At least, as remarked before, it has been used very little. Curiously, it happens that most investigators desiring knowledge of the capacitance of a certain configuration have utilized the same experimental setup for mapping the electric field and have then determined from the graphical field map—hence indirectly and with loss of accuracy—the desired capacitance. This procedure is typified in the work of Sacchetto.[10]

Experimental Apparatus

Figure 2 illustrates the apparatus utilized for the experimental work. A glass evaporating dish ten inches in diameter and four inches high contains the conducting medium. After testing several fluids, distilled water was selected as most satisfactory for general use. It is both inexpensive and easily procurable, and it affords a range of resistance which enables accurate measurement on an ordinary 4-decade Wheatstone bridge.

The circular brass electrodes, four inches high, are cut from standard sizes of brass tubing. The rectangular copper electrodes, 2.25 inches high, are made from copper strips, cut from standard 1/16-inch copper sheeting, bent to size in a mechanical bending machine, and brazed together at the joint. The internal and external dimensions of the circular electrodes are tabulated in Table I; those of the rectangular electrodes are tabulated in Table II.

The terminals of the bridge are connected to the electrodes by leads terminated in alligator clips. The total series resistance of leads, clips, and a typical pair of electrodes is less than 0.1 ohm, a quantity which is negligible by

Figure 2. Experimental apparatus

Figure 4. Capacitance per centimeter length of capacitor

comparison with the several hundred or several thousand ohms of the conducting medium between the electrodes.

In use, the height of the conducting medium is measured with a steel scale. Coaxialness of the electrodes is assured by placing beneath the glass container a sheet of paper on which the properly located cross sections of the electrodes (circular or rectangular, as used) are drawn to size.

The electrodes, polished with fine emery cloth, are prepared for use by immersing them in a dilute solution of hydrochloric acid for ten minutes; then removing the drops of solution clinging to their surfaces by thorough scrubbing with a stiff brush under running water; and finally soaking them in distilled water for 24 hours, during which time the small traces of acid yet remaining in fine cracks or minute pits in the surface of the electrodes pass into the distilled water. During cleaning, and during the experimental work, the electrodes are handled with tongs to avoid possible contamination of the surfaces by dust, body acids, or other substances commonly present on the worker's hands.

A considerable amount of experimentation was required to obtain a conducting medium of constant resistivity. Preliminary runs with the circular electrodes revealed that the resistivity of the distilled water, if used as obtained directly from a chemical store room, changed rather rapidly with time. For example, two runs made three hours apart on the same setup, revealed that the resistivity had changed 18 per cent during this period. Initially, this change of resistivity with time was attributed to one or more of the following causes:

1. Contamination of the water by particles of dust settling in it from the atmosphere or by absorption of gases from the atmosphere.

2. Contamination of the water by particles of dust which settled on the electrodes while they were not in use.

3. Electrolysis or polarization produced by the d-c bridge current passing through the possibly slightly impure distilled water.

Systematic exploration of these possibilities resulted in finding

1. That the distilled water should be kept in a large glass beaker, but with the open top covered with paper, so that the water is protected from the dust, yet essentially is open to the atmosphere insofar as absorption of gases is concerned. This is allowed to stand for approximately 36 hours so that it comes into equilibrium insofar as appreciable change in resistivity over the considerable time required to take a large set of experimental readings is concerned.

2. That to avoid contamination of the water by dust collected on the electrodes and to avoid disturbing the stableness of the water, it is desirable to keep those electrodes not in use in the water just mentioned (or in glass beakers of water prepared at the same time and in the same fashion).

3. That essentially identical readings are obtained with either d-c or a-c Wheatstone bridges. As d-c bridges are somewhat more advantageous for general work, all data was obtained with a commercial 4-decade d-c bridge.

Experimental Data

Five runs were made. Run 1, on circular electrodes, enables calculation of the resistivity of the conducting medium, provides experimental confirmation of the general method, and furnishes a check on the correct functioning of the apparatus. The data, taken with a fixed outer electrode and inner electrodes of various radii, are tabulated in Table I.

Runs 2, 3, and 4, on rectangular electrodes enables derivation of a general equation for the capacitance of a coaxial cylindrical capacitor of square cross section and yield data for families of curves furnishing the capacitance of a wide range of cylindrical capacitors of general rectangular cross section. The data taken with fixed outer electrodes (ratio of ex-

ternal sides $d/c=1$, 1.23 and 1.67) and inner electrodes of various sizes are tabulated in Tables III, IV, and V.

Run 5, on square electrodes, provides experimental confirmation of a point of general theory effected by dimensional analysis, which is of general importance in calculating capacitance. The data are tabulated in Table VI.

Calculation of Resistivity

From well known theory[8] the resistance R of a length L of the conducting medium between two indefinitely long, coaxial circular cylindrical electrodes is

$$R=(\rho/2\pi L)\ \ln\ (r_2/r_1)\ \text{ohms} \qquad (2)$$

wherein r_1 is the radius of the inner electrode, r_2 the radius of the outer electrode, and ρ the resistivity of the conducting medium between the electrodes Accordingly, if $R_u=RL$ (where R_u is numerically equal to the resistance of a unit length of the cylindrical configuration).

$$R_u=(\rho/2\pi)\ \ln\ (r_2/r_1)\ \text{ohm-centimeters} \qquad (3)$$

Inasmuch as r_2/r_1 is a dimensionless ratio, r_1 and r_2 can be measured in any convenient unit of length. If, as is usually desirable, R is to be measured in ohms and R_u in ohm-centimeters, ρ must be measured in ohm-centimeters.

Equation 3 can be written in the form

$$R_u=-(\rho/2\pi)\ \ln\ r_1+(\rho/2\pi)\ \ln\ r_2\ \text{ohm-centimeters} \qquad (4)$$

In equation 4, let r_2 be of fixed value and the equation be interpreted as expressing R_u as a function of $\ln\ r_1$. Then equation 4 is that of a straight line, whereof $(-\rho/2\pi)$ is the slope m and $[(\rho/2\pi)\ln\ r_2]$ is the ordinate intercept B. Accordingly, if the resistances between a fixed outer electrode of radius r_2 and various inner electrodes of radius r_1 be measured, and if from this data R_u is plotted as a function of $\ln\ r_1$, it is to be expected that the resulting curve will be a straight line.

The curve of Figure 3, plotted from the data of run 1, made in the manner stated, is precisely such a straight line. Accordingly, as in run 1, $r_2=6.99$ centimeters, the equation of this straight line is

$$R_u=-0.159\rho\ \ln\ r_1+0.310\rho\ \text{ohm-centimeters} \qquad (5)$$

The slope m of this straight line is -0.159ρ; the ordinate intercept B is 0.310ρ. In consequence, $\rho=m/(-0.159)=B/0.310$ ohm-centimeters. From Figure 2 the value of B is 40,600. Therefore, $\rho=40{,}600/0.310=1.31\times10^5$ ohm-centimeters. Corroboratively, measurement of ρ with a standard conductivity cell yields essentially the same value.

These several agreements between theory and experiment indicate that the apparatus is functioning correctly and provide, as is discussed in the next section, experimental confirmation of the general procedure outlined under Fundamental Theory.

Square Cylindrical Capacitors

Substituting $\rho=1.31\times10^5$ ohm-centimeters, $\epsilon_o=(1/36\pi)10^{-11}$ farads/centimeter*, and $\epsilon_r=1$ in equation 1 yields

$$C_o=1.16\times10^4/R_u\ \text{micromicrofarads/centimeter} \qquad (6)$$

where C_o indicates the capacitance per centimeter length of the capacitor with *air* as dielectric. Correspondingly, the elastance $S_o=1/C_o$ is

$$S_o=8.67\times10^{-8}R_u\ \text{megamegadarafcentimeters} \qquad (7)$$

Values of the capacitances C_o and of the elastance S_o of circular cylindrical capacitors, calculated from the data of run 1, are tabulated in Table I. Values of the capacitance C_o and of the elastance S_o of square cylindrical capacitors, calculated from the data of run 2, are tabulated in Table VII. These two sets of data afford the curves of Figures 4 and 5.

In Figure 5, the straight line obtained for the circular cross section is that of the

known equation for the elastance of a circular cylindrical capacitor, $S_u = (1/2\pi\epsilon)\ln(r_2/r_1)$.

Obviously, this agreement between theory and experiment is to be expected: for the same experimental data affords the theoretically predicted curve of Figure 3. But it is a new and most interesting result that over the range of b/d utilized in the experimental work the curve for the square cylindrical capacitor is also a straight line.

Scaling the slope of this straight line yields $m = 1.532 \times 10^{12}$. Accordingly, its equation is

$$S_u = 1.532 \ln (d/b) \text{ megamegadaraf-centimeter} \tag{8}$$

If the slope is written in the form $m = k/2\pi\epsilon_0 = 1.532 \times 10^{12}$, the substitution of $\epsilon_0 = (1/36\pi)10^{-11}$ yields $k = 0.852$. Hence, the experimentally determined equation of the elastance of a square cylindrical capacitor, written in a form paralleling the theoretically derived equation for the elastance of a circular cylindrical capacitor, is

$$S_u = (1/2\pi\epsilon) \ln (d/b)^{0.852} \text{ daraf-centimeters} \tag{9}$$

*In meter-kilogram-second units as used in this paper, the absolute permittivity is $\epsilon_0 = (1/36\pi)10^{-9}$ farad per meter, whence the value of $(1/36\pi)10^{-11}$ farads per centimeter used above.

and the corresponding equation for the capacitance is

$$C_u = 2\pi\epsilon/\ln (d/b)^{0.852} \text{ farads/centimeter} \tag{10}$$

Equations 9 and 10 are, therefore, general equations from which the elastance and the capacitance of a square cylindrical capacitor of arbitrary dimensions can be calculated *for* (as is shown in the next section) all values of the ratio d/b which are likely to be encountered in practice.

Analytic Substantiation of Equation 10

Polya and Szego[11,12] have shown that the capacitance C_u of a cylindrical capacitor whereof the cross section is the annular area bounded by two similar, that is, the ratio of corresponding sides is a constant) concentric parallel-sided polygons of n sides lies between the limits

$$\sum_{i=1}^{n} \epsilon A_i/D_i \leq C_u \leq \frac{L'-L}{L \ln (L'/L)} \sum_{i=1}^{n} \epsilon A_i/D_i \tag{11}$$

whereof A_i is the length of a side of the inner polygon, D_i the perpendicular distance of this side from the corresponding side of the outer polygon, L is the length of the perimeter of the inner polygon, and L' is the length of the perimeter of the outer polygon. In the case of a square capacitor of inner side b and outer side d, $D_i = (d-b)/2$, $A_i = b$, $L = 4b$ and $L' = 4d$. Substituting in equation 11 yields

$$8\epsilon b/(d-b) \leq C_u \leq 8\epsilon/\ln(d/b) \tag{12}$$

Rewriting equation 10 in the form of the upper bound of equation 12 gives

$$C_u = 7.37\epsilon/\ln(d/b) \tag{13}$$

The values of the upper and lower bounds of equation 12 and the values of C_u from equation 13, as calculated from the data of Table VII (the data used in plotting the curve of Figure 5 from which equation 13 stems), are tabulated in Table VIII. Over the experimental range of d/b the values from equation 13 fall between the upper and lower bounds, hence are limited in accord with theory. It is to be noted that over this range of d/b (3 to 15) the theoretical lower bound is very poor. This condition is to be expected; for this lower bound is an obvious approximation stemming from the equation for the capacitance of a parallel plate capacitor, hence is a good approximation only for small values of $(d-b)/2$, thus for values of $d/b \cong 1$. Solving the equation $8b/(d-b) = 7.37/\ln(d/b)$ by trial yields $d/b = 1.15$. Accordingly, for all values of d/b greater than 1.15, hence certainly for all values to be encountered in practice, equation 13 yields values between the theoretical limits. Accordingly Polya and Szego's analysis provides striking mathematical evidence of the correctness of the experimentally derived equation.

In view of this confirmation, and in view of the excellent linearity of the experimental data, it can safely be said that equation 13 can be used to calculate the values of the capacitances of those square cylindrical capacitors likely to be encountered in practice. In substantiation of this statement are to be noted the capaci-

Figure 6. Elastance of a centimeter length of capacitor: $d/c = 1$

Figure 7. Capacitance per centimeter length of capacitor: $d/c = 1$

Figure 8. Elastance of a centimeter length of capacitor: $d/c = 1.23$

tances C_u of two square capacitors of ratio of sides $d/b=2$ and $d/b=3$. These values, computed in connection with another part of the thesis from which this paper stems, were calculated in well known fashion from flux plots effected with considerable accuracy by a finite difference procedure, the so-called relaxation process.[13] The two values are 0.925 and 0.536 micromicrofarad per centimeter; the corresponding values from equation 13 are 0.975 and 0.575 micromicrofarad per centimeter. The per cent differences in corresponding values are 4.1 and 6.8 per cent. In view of the difficulty associated with accurately calculating capacitance from a flux plot, the agreement of corresponding values is excellent; further, it is to be expected that the values calculated from equation 13 are the more correct values.

Rectangular Cylindrical Capacitors

The geometry of a rectangular cylindrical capacitor with cross section as in Figure 1 is completely determined by knowledge of one side of the cross section and the ratios of the other sides to it; for example, by d, d/a, d/b and d/c. Now as in meter-kilogram-second units C_u is of dimensions farad-meter^{-1} and ϵ is also of dimensions farad-meter^{-1}, it follows from the theory of dimensional analysis[14] that the capacitance C_u of a rectangular cylindrical capacitor can be written in the form

$$C_u = \epsilon F(d/a,\ d/b,\ d/c) \tag{14}$$

where F is an unknown dimensionless function of the ratios d/a, d/b, and d/c.

Equation 14 indicates that rectangular cylindrical capacitors can be of different dimensions a, b, c, and d, yet if the ratios d/a, d/b, and d/c are alike, the capacitors will be of identical capacitance. Corroboratively, for each of three different sets of ratios, the two or three corresponding values of C_o tabulated in Table VI (from data taken in run 5) are in excellent agreement.

The slight discrepancies are attributable to experimental error inherently imposed by the slight difference in corresponding like geometric ratios.

This excellent agreement between theory and experiment provides further, and striking confirmation of the reliability of the direct experimental methods of determining capacitance.

Figure 10. Elastance of a centimeter length of capacitor: $d/c = 1.67$

Cylindrical Capacitors of Arbitrary Dimensions

It follows from equation 14 that a 4-dimensional plot of capacitance as a function of the three ratios d/a, d/b, and d/c would yield the capacitance of a rectangular cylindrical capacitor of arbitrary dimensions. A systematic method of obtaining the required experimental data for such a plot is to hold, in turn, two of the ratios fixed and to vary the third over any desired range. Of course, the data so obtained cannot be obtained in a 4-dimensional space. But for engineering purposes it suffices to plot the data by preparing curve sheets whereon for a given ratio of d/c a parametric family of curves of C_o or S_o are plotted as functions of d/b, the parameter being d/a. Figures 6 to 11, prepared from the data of Tables 3, 4 and 5, comprise precisely such families of curves. The dashed lines, drawn through the data points for square capacitors, afford a check on the experimental values. For as in Figure 5, these points fall on a

straight line in accordance with the theory discussed under Square Cylindrical Capacitors. In a similar fashion, a set of curves can be prepared for any shape of cylindrical capacitor and over as great a range of geometry as is desired. In particular, it would be a simple matter to prepare a set of curves for the capacitance of a coaxial line comprised of an outer conductor of rectangular cross section and inner conductor of circular cross section. This configuration, of importance in communication work, is intractable to exact analytic solution; and existing approximate equations for the capacitance, obtained by intricate mathematical analysis, are valid for only a limited range of geometry.[15,16]

Capacitors of Arbitrary Geometry

From well-known theory, the problem of determining the capacitance of a capacitor comprised of plates of arbitrary geometry, arbitrarily located relative to one another, and containing dielectric which, though homogeneous throughout a region, may vary in permittivity from one region of space to another, hinges on determining a potential function V that:

1. Satisfies Laplace's equation everywhere in space.
2. Vanishes at infinity, except possibly for a constant.
3. Takes on assigned constant values over each of the plates.
4. Satisfies the equations $V' = V''$ and $\epsilon'(\partial V'/\partial n) = \epsilon''(\partial V''/\partial n)$ at each point in the interface between two regions of permittivity ϵ and ϵ'', n being the outward normal to the interface.

The potential V being obtained, the surface integral of $\epsilon(-\partial V/\partial n)$ over one of the plates yields the charge on the capacitor; whence the ratio of this charge to the known potential difference yields the desired capacitance.

Correspondingly, the problem of determining the conductance between two electrodes of arbitrary geometry, arbitrarily located relative to one another, and immersed in a conducting medium which, though homogeneous throughout a region may vary in conductivity σ from one region of space to another, hinges on determining a potential function V satisfying conditions precisely the same as those shown before except for the replacement of ϵ by σ. The potential V being determined, the surface integral of $\sigma(-\partial V/\partial n)$ over one of the electrodes yields the current between the electrodes; whence the ratio of this current to the potential difference yields the desired conductance. Accordingly, the top problems are mathematically identical and knowledge of one yields the other through appropriate interchange of ϵ and σ. In consequence, it follows that the direct experimental method of determining capacitance is not confined to cylindrical capacitors, but can be utilized for any shape of capacitor by obvious extension of the procedure outlined previously.

Inductance of High Frequency Transmission Lines

It is well known[9] that the inductance L_u and the capacitance C_u of a high-frequency transmission line are related by the equation $L_u C_u = \mu\epsilon$. Substituting from equation 1 yields

$$L_u = (\mu/\rho) R_u \tag{15}$$

Accordingly, the inductance of such a line can be determined experimentally in the fashion discussed before. This method ought to be particularly useful for obtaining the inductances of configurations of split-conductor transmission lines such as four- or eight-wire exponential transmission lines.

Discussion

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.): I note with much interest the paper by Teasdale and Higgins in the determination of capacitance by the use of resistance measurements. In our work to which the authors refer, we found possible far greater precision than for other methods. Not only was good precision obtainable but the method is more simple and rapid in use than alternate physical methods that have been pursued.

There is little more to be said in discussion of a paper such as this than that the work appears to have been carried on efficiently and that the results have been presented in a manner to make them readily and widely available for the purpose intended.

An Optical Radar for Surveying

W. W. HANSEN
NONMEMBER AIEE

Synopsis: An instrument is described which uses radar techniques to make a survey of terrain. Distances are determined by measuring the transit time of pulses of light traveling between the instrument and a retrodirective reflector placed at the point whose relative position is to be found. Angles are measured by adjusting the position of the optical transmitter to obtain a maximum pip on a cathode-ray tube.

Introduction and General Description

THE instrument is capable of making a survey of terrain when conventional survey methods would be too slow or when long traverses over inaccessible terrain are needed. The choice of light instead of microwave radar was made because of the improved resolution and because reflections of microwave radar from other than the target would limit the usefulness of the equipment.

In the method used, distance or range is determined by measuring the transit time of pulses of light traveling to and from a retrodirective reflector placed at a point whose relative position is to be found. Angles are determined by adjusting the position of the optical transmitter to produce a maximum return "pip" on a cathode-ray tube. While the accuracy of the survey which can be obtained with this instrument is not as good as that which can be achieved by conventional surveying methods, it does compare favorably with the accuracy of a third class survey.

A block diagram illustrating the overall method of operation of the device is shown in Figure 1. When the flashlamp in the optical transmitter breaks down, it triggers the sweep generator which causes a trace to appear on the cathode-ray tube. The light pulse transmitted by the lamp is returned from the distant reflector and falls on the cathode of the photomultiplier, causing a pip to appear on the trace. Upon returning to its normal state, the sweep generator triggers the second sweep timer which gates the range and trigger pip generators. These produce a second trace displaying range pips which can be matched with the target return pip by adjustment of the phase shifter.

When the second trace is completed, the circuits return to their normal states and are ready to repeat the cycle when the lamp flashes again.

A view of the instrument, assembled and ready for use, is shown in Figure 2. It will be noted that the instrument consists of four main units in addition to the batteries. These units will be called the optical head, the scope unit, the main power supply, and the converter unit.

The optical head is mounted on a tripod and contains the flashlamp and optical system necessary for transmitting the light from the lamp, receiving it from the distant reflector, and focusing it on the cathode of a photomultiplier. The output of the photomultiplier is amplified by a two-stage amplifier which is also part of the optical head and is contained, with the multiplier, in a chassis attached to the rear of the mirror housing. The optical head is mounted on bearings attached to graduated circles to permit its elevation and rotation to be determined within one minute of arc.

The output of the amplifier is fed through a delay line to the scope unit where it is amplified by two additional stages of amplification to produce the vertical "pip" on the cathode-ray tube. The scope unit is mounted on top of the main power supply during operation and can be tilted for the convenience of an operator seated in front of it. This unit contains, in addition to two stages of vertical amplification and the cathode-ray tube, the sweep circuits and other circuits necessary for the precise determination of range. A front view of the panel of this unit is shown in Figure 3.

The entire equipment is designed to operate from 110 volts, 60 cycle a-c or from 12 volts direct current. When d-c operation is desired, a 12 volt d-c to 110 volt a-c rotary converter contained in the converter unit is used. This unit also contains a neon sign transformer and rectifier to operate the flashlamp. The flashing rate of the lamp is controlled by varying the voltage fed to the primary of the neon sign transformer by means of a variac located in the main power supply. This unit supplies the plate and accelerating voltages to the tubes in the scope unit and in the optical head.

During operation the operator can turn the optical head by means of flexible shafts attached to cranks which fit on the scope unit. The electrical cables connecting the units during operation are stored in a compartment attached to the bottom of the scope unit when the units are packed for transportation. The sizes and weights of the units are such that they can be manborne.

Optical System

A schematic, cross-sectional view of the optical system is shown in Figure 4. The focal point of the parabolic mirror coincides with the center of the arc at point F so that an image of the arc is formed at infinity. The light returning from the target is focused on the pinhole or slit at point F' and then passes through the

Paper 48-113, recommended by the AIEE communication committee and approved by the AIEE technical program committee for presentation at the AIEE Great Lakes District meeting, April 1-3, 1948. Manuscript submitted November 12, 1947; made available for printing February 25, 1948.

center of the parabolic mirror to the cathode of the photomultiplier. A slit is used at point F' for ease in "finding" the target when a search is being made for it; the pinhole is used for angular definition after the target has been found.

Ranging Method

The range accuracy requirements led to the adoption of a ranging scheme which involves the comparison of light transit time with the period of a crystal-controlled oscillator. An essential part of this scheme is a device which shifts the phase of the oscillator output to permit the matching of range pips to the target return pips. While no originality for this idea can be claimed here, its application to an optical transmitter involved special problems in synchronization. A similar scheme was used in the *AN/MPG-1* radar.[1] The process of pulsing a radio transmitter at a given instant is fairly straightforward and precise, but some concern was felt about the feasibility and possibility of triggering a gas discharge lamp within a very small fraction of a microsecond of a desired time, especially in view of the size and weight restrictions on the equipment. Instead of initiating the flashes of the lamp in synchronism with the oscillator, it would have been fairly easy to have started and stopped an oscillator in synchronism with the flashlamp but this usually entails some sacrifice in oscillator stability as compared to that of a free-running crystal oscillator and also introduces transient errors in the phase shifter.

These problems were avoided by the use of circuits which cause two traces to appear on the scope for each flash of the lamp. The first trace starts when the lamp flashes and displays the target return pip; the second trace starts about 0.01 second later and in synchronism with the oscillator. The second trace can be shifted vertically relative to the first one and displays a series of ranging pips which can be moved horizontally by means of the phase shifter until one of them matches the target return pip. The appearance of the scope screen when pips are matched is shown in Figure 5. The frequency of the oscillator is such that the interval between successive ranging pips corresponds to a range interval of 500 yards. A coarse range switch permits the interval containing the target pip to be brought to the center of scope screen where it is expanded to give greater

Figure 2. Assembled instrument, ready for use. Front view

Figure 3. Panel of scope unit. Main electronic unit (front panel)

Figure 4. Cross section of optical system

Figure 5 (above). Appearance of scope when pips are matched

matching accuracy. When pips are matched the range is the sum of the readings of the coarse range dial and the fine range dial. The coarse range dial is marked in steps of 500 yards; the fine range dial is attached to the shaft of the phase shifter and is graduated from 0 to 500 yards at intervals of one yard.

Sweep Generator and Sweep Amplifier

The schematic circuit diagram of the sweep generator and sweep amplifier is shown in Figure 6. To aid in the understanding of the operation of these circuits the flash lamp circuit is also shown in this figure although these components are not included in the scope unit. The sweep generator is a cathode-coupled flip flop circuit whose holding time is about 35 microseconds. The sweep amplifier is a cathode-coupled push-pull amplifier which is direct-coupled to the horizontal deflection plates of the cathode-ray tube. When the capacitor, C_1, is charged to a potential equal to that of the breakdown of the spark gap the lamp discharges it and, in doing so, applies a positive pulse to the left grid of T_1. This causes the normally conducting right half of the tube to be cut off for a time which is determined mainly by C_2 and R_1. When T_1 is triggered the potential difference across C_2 increases and causes the left grid of T_2 to become more positive. The change in potential across C_2 is considerably larger than that necessary to drive the left half of T_2 from cut-off to saturation, consequently the cathode spot moves across the cathode-ray screen only during a portion of the time that C_2 is charging. The time at which the sweep starts is determined by the setting of the coarse range switch which adjusts the bias on the left grid of T_2. If this grid were returned directly to ground, it would always be biased considerably beyond cut-off by the current flowing through the right half of the tube and the cathode resistor, R_2.

When T_1 is triggered the potential of its cathode drops abruptly. This change in potential is amplified by a deblanking stage and applied to the intensity grid of the cathode-ray tube, allowing the cathode spot to appear as long as T_1 is in its triggered state.

When the target is being searched for, a range-search switch (not shown in Figure 6) is turned to the search position. This places another capacitor in parallel with C_2 and biases T_2 so that the sweep starts at the instant the lamp flashes and the spot continues to move across the screen at a fairly uniform rate during the entire 35 microseconds sweep time. In this switch position, the second trace does not appear.

Second Sweep Timer and Trigger Pip Generator

When T_1 (Figure 6) returns to its normal state the potential of its cathode rises abruptly to about 50 volts and then drops rapidly to its normal potential of about 20 volts. This abrupt rise in potential is used to trigger the second sweep timer which is a flip flop circuit with a holding time of about 0.01 second. The schematic circuit diagram of the second sweep timer and the trigger pip generator is shown in Figure 7. The output of the os-

Figure 6 (above). Schematic circuit of sweep generator and sweep amplifier

Figure 7. Schematic circuit of second sweep timer and trigger pip generator

Figure 8 (above). Schematic of gating circuits

Figure 9. Schematic of phase shifter and phase-splitting circuits

cillator is sufficient to overload T_1, causing its output to approximate a square wave. This is differentiated so that the signal appearing at the grid of T_2 is a series of alternately positive and negative pulses. Tube, T_2, is normally biased sufficiently to prevent any signal from appearing at its plate. However, when T_2 returns to its normal state its cathode potential rises abruptly, producing a pedestal voltage at the control grid of T_3 and allowing a pulse to trigger the sweep generator and initiate the second sweep. When the sweep generator returns to its normal state it does not trigger the second sweep timer again because the cathode potential of the second sweep timer does not drop sufficiently during the 35 microsecond second sweep interval.

Gating Circuits

When the second sweep timer is triggered at the completion of the first sweep, the drop in potential of its left plate is used to actuate gating circuits which shift the second trace vertically relative to the first and allow marker pips to appear on the second trace. These circuits also cut off the vertical amplifier during the second trace to prevent noise from appearing on it. The schematic diagram of the gating circuits is shown in Figure 8. The cathode-ray circuits are shown for clarity but only a portion of the range pip generator is shown because it is similar to the trigger pip generator except for an additional stage of amplification to compensate for the phase shifter attenuation.

The values of the resistors, R_1 and R_2, are chosen to apply a positive potential to the grid of T_2 when the second sweep timer is in its normal state. The cathode current of T_2 biases T_1 beyond cut-off so that no signal appears at its plate. The plate current of T_2 flows through the center-tapped potentiometer, R_5, and produces a difference in potential between the vertical deflection plates of T_4 whose magnitude and sign depend on the position of the slider relative to the center-tap and thus determines the position of the first trace relative to the second. When the second sweep timer is triggered, tube T_2 is biased beyond cut-off. This releases some of the bias on T_1 and allows a signal consisting of a series of negative pulses to be applied to one of the vertical plates of T_3 and cuts off the plate current which flowed through R_6 during the first trace. Capacitor C_1 insures that tube T_2 remains cut off during the second trace.

Resistors R_3 and R_4 are chosen so that the final stage of the vertical amplifier is biased beyond cut-off during the second trace but is biased normally during the first. Capacitor C_2 insures that the vertical amplifier remains cut off during the second trace.

Phase Shifter

The schematic circuit diagram of the phase shifter and of the phase spitting circuits which supply it is shown in Figure 9. The phase shifter is a special capacitor consisting of four quadrants which induce voltages in a common pickup plate which faces them. The theory of operation and a discussion of the errors of the phase shifting capacitor are given in other publications.[2,3] These capacitors are made by the P. J. Nilsen Company, Oak Park, Ill. An eccentrically mounted, circular, mycalex disk is mounted between the quadrants and the pickup plate so that the capacitance between each quadrant and the pickup plate varies as the disk is rotated. One mechanical degree of shaft rotation produces one electrical degree of phase change in the vector sum of the voltages induced in the pickup plate provided the quadrants are supplied with voltages of equal amplitude but in phase quadrature. This situation will exist if the reactances of capacitors C_1 and C_2 (Figure 9) are equal to the resistances of R_1 and R_2 at the oscillator frequency and if the network is balanced to ground. The capacitor, C_3, provides a balance to ground by compensating for the interwinding capacitance between L_1 and L_2.

Vertical Amplifier

The vertical amplifier has a voltage gain of about 85 decibels and is shunt compensated to a top frequency of two megacycles. A delay line between the second and third stages serves as a flexible coupling between the optical head and the scope unit and delays the signals sufficiently to allow range readings to be made on very close targets. In fact, the zero adjustment of the phase shifter shaft is made by holding a reflector next to the framework of the optical head and in the light beam. This permits a ready determination of the zero correction in the field.

A Large-Scale General-Purpose Electric Analog Computer

E. L. HARDER
MEMBER AIEE

G. D. McCANN
MEMBER AIEE

OVER the past ten years computation by the electric analog method has come into increased use in the solution of transient problems in the fields of electric circuits[1,2,3] and machinery, and in applied mechanics,[4–9,12] hydraulics, and heat flow.[5] It has also been found admirably adapted to the study of electromechanical systems such as servomechanisms[10,11,13,15] and controls.[14] These developments have been reported in previous papers before the Institute and elsewhere.

A little over two years ago a survey was made to determine the general field of problems which could be solved by the electric analog method, special emphasis being placed on the design and application of electrical equipment. Both electrical and mechanical problems were considered. At the same time a study was made of the various other types of computers both present and proposed which might be applied to the solution of these problems. As a result of this survey, it was decided that the electrical analog computer was best adapted generically and economically to the scope of problems under consideration and it was decided to build a general purpose computer along these lines which would be able to handle a great majority of these problems.

Generally speaking, the new computer was to incorporate the facilities of the electrical[1] and mechanical[8] transients analyzers, and the servoanalyzer[12] previously described, together with new facilities to form a general purpose computer. The new facilities included principally multipliers, transformers of special design, and forcing functions of the independent variable as well as non-linear functions of the dependent variable.

It was decided to redesign all existing elements to eliminate weaknesses and limitations found through experience ranging from a few months up to 10 years on various parts of the small-scale computer. Furthermore, the facilities for connections should be greatly improved and control desks designed to expedite measurements and give the operators continuous control of elements requiring frequent change throughout a problem. For economy of loading two control desks were to be provided and the facilities arranged for simultaneous solution of two or more problems.

Several months after the design of the Westinghouse computer was undertaken, arrangements were made for a similar computer to be installed at the California Institute of Technology, and for further development work to be shared.

The resulting two computers are alike in all essential features and general design, differing only in minor matters of construction and in the exact number of each kind of element installed. These differences are dictated largely by the principle uses contemplated for the respective computers.

Description of the Computer

1. Principle of Operation

In order to understand the purposes of the various elements, it will be necessary to outline briefly the operation of an electric analog computer. For a more detailed exposition of the theory the reader is referred to previous papers and articles listed at the end of the paper, particularly references[1,4,8,12]. These papers give the general theory of the repetitive method of solving transient problems, and the theory of analogs and their use in electrical computers. As shown in Figure 1 the computer can be divided into three principle parts, namely, the forcing functions, the analog of the system being studied, and the measuring equipment. The analog is formed by connecting circuit parameters, R, L, and C, together with amplifiers and transformers and multipliers into a circuit which has the same differential equation as the system under consideration.

In a transient problem, it is frequently desired to determine the response of a system to some applied force or disturbance or to some change in a circuit parameter. The forcing function must generate this force in the form of a voltage or current and apply it to the electric analog of the system.

The forcing function may be applied repetitively by a synchronous switch. Thus the solution, which also repeats, can be displayed on a cathode-ray oscillograph for visual or photographic measurement.

Typical steady-state and transient problems are illustrated in Figures 1(c) and (d). The steady-state problem is a torsional vibration analysis. The forcing function is then a variable frequency power source, representing possible exciting forces. The mass-inductance analog is used in which voltage corresponds to torque and charge to angular displacement. The susceptance of the capacitor is proportioned to the spring constant of the shaft.

The solution in this case is expressible as torque build-up. By measuring the ratio of capacitor voltage to input voltage by cathode-ray oscillograph and attenuator or by a voltmeter, the ratio of shaft torque to input is obtained.

In the transient problem Figure 1(d) the electric torque exerted at the air-gap

Manuscript submitted November 21, 1947; made available for printing February 10, 1948.

E. L. Harder is consulting transmission engineer, industry engineering department, Westinghouse Electric Corporation, East Pittsburgh, Pa., and G. D. McCann is professor of electrical engineering, California Institute of Technology, Pasadena, Calif.

of a turbogenerator during short circuit is a complex wave. It contains three components of different frequencies and decrement. These are generated by capacitor discharge in oscillatory circuits of corresponding frequencies. The resulting currents are passed through a common slide wire resistor to obtain a "forcing function" voltage having the required shape.

The analog is the same as for the steady-state problem. However, the measuring equipment in this case consists of cathode-ray oscillograph. Maximum torque in the shafts can be read visually or the entire plot of torque versus time photographed. Figure 2 shows the wave shapes involved.

These sample cases illustrate the principle of operation. In practice many of the analog circuits are more complicated, some requiring several hundred circuit parameters for adequate representation. Many different types of forcing functions are required. Special transformers, amplifiers, multipliers and nonlinear functions are needed for the analog elements. Various metering methods are required depending on the nature of the problem. Also a rapid and flexible arrangement is needed for connecting and checking the circuits and metering all parts of the problem. The subsequent paragraphs will outline the general arrangement which has evolved and describe the various elements and the application of the computer.

2. General Arrangement of the Computer

The general arrangement of a large scale computer is dictated by the considerations of maximum utility and flexibility and minimum operating difficulties and maintenance. This requires consideration of shielding, and of the length of leads. It requires provision of flexibility for handling a large variety of problems and accessibility of all parts for maintenance. In the case of a two-desk computer the least possible interference should be occasioned when two problems are going on simultaneously. On the computer a wide variety of impedances and frequencies are involved. For this reason, particular attention must be given to the shielding and stray capacity and inductance effects. The new computers have been designed to provide an optimum arrangement with all of these factors considered.

The number of units of each type required for a general purpose computer is dictated by economics, by experience, and by forecasts of requirements for the general class of problems which it is expected to handle. The compositions of the Westinghouse and California Institute of Technology's computers is given in Appendix I.

The general arrangement of the computers is indicated in Figure 3. The Westinghouse computer is located in a room adjacent to the a-c calculating board to provide the benefits of interchange between the transient and steady-state computers. The circuit element cabinets are arranged along one wall of the computer room, interspersed with plugboards upon which the connections are made to form the analog and forcing function networks. An electronic power supply cabinet is located in the center of this row of cabinets, while the 440-cycle power supply, being noncritical to lead length, is located along the opposite wall.

Amplifier and multiplier cabinets are at one end of the room adjacent to metering desk 1. This desk will normally handle the servo and control system type of problems. Desk 2 at the other end of the computer room will normally handle power system problems, using the 440-cycle supply, as well as transient torque problems, and others not requiring the electronic equipment. However, the amplifier cabinets have been made portable so that they can be divided in any desired manner between the two metering desks. One or more of the cabinets can be moved physically to the location of the second desk in order to make electronic analogy set-ups without extensive leads.

Time delay elements consisting of variable resistance and capacitance are included in the several amplifier cabinets so that servo and control system problems can in critical cases be set up entirely within the confines of the amplifier cabinets.

The California Institute computer differs from the Westinghouse unit in composition, as indicated in Appendix I. Also its arrangement is somewhat different. Figure 5 shows a general view of the California Institute's computer. Since it is not to be operated in conjunction with a separate a-c calculating board, it has been designed so as to be suitable for electric power system problems. At present only one metering desk and one forcing functions cabinet is in use. However, the heavy schedule under which it has been operating indicates the need of an additional control center. One more metering desk and forcing functions cabinet will probably be added. Twenty-five main busses run throughout the computer. These are sectionalized at the two corners, Figure 3(b), so that the three sides can be used separately for simultaneous setting up two or more problems. However, all of the general development, the component element electrical designs, the principles of shielding, the power levels, ranges, accuracies, wiring and selection principles are the same for these two computers.

The general wiring plan of the Westinghouse computer is shown in Figure 4. Circuit parameters, R, L, and C, as well as

Figure 2. Transient torques in shaft and coupling due to a line-to-line short circuit of a generator

transformers and all power supplies are brought out to plugs or receptacles on the interspersed plug-boards. This is indicated by the lines from the *A* cabinets, containing these elements, to the plugs indicated by arrows on the front of the plug-board cabinets, *B*. Connection panels, on the plug-boards *B*, are provided with receptacles (not shown) arranged in rows and so wired that all plugs in adjacent receptacles are automatically connected together. Analogs are made up by plugging together the appropriate circuit elements on the plug-boards.

To provide flexibility for the use of remotely located elements of the computer, a 48-wire relay bus runs to all plug-boards. A 20-wire bus to the development area provides flexibility for development of additional forcing functions and circuit elements and their use in connection with the computer.

A 60-wire relay interconnects the electric analog computer with the a-c calculating board. In addition the 440-cycle power supplies, cabinet *J*1, are arranged for transfer to use either with the analog computer as indicated by terminals coming out on the plug-boards, *B*, or with the a-c calculating board. Remote control of magnitude and phase position (not shown) is available from the a-c calculating board room.

Amplifier-multiplier cabinets are equipped with small integral connection boards which minimizes the extent of wiring. They have also 20-wire busses brought out to receptacles which interconnect through plug cords from cabinet to cabinet and to the circuit element board.

From his operating location at metering desk *D*-1, or *D*-2, the operator is able to adjust the synchronous switch stages, and select the locations in the analog across which oscillographs and synchronous switches are connected. He can meter any analog circuit, insert and adjust damping resistors, control magnitudes of key parameters, and control the forcing functions.

These facilities are made available by a variety of control and circuits indicated schematically in Figure 4. Synchronous switch to bus, selectors, and damping resistors are mounted in cabinets integral with the synchronous switches, H-1, H-2 and H-3. The other controls and instruments are part of the metering desk.

Each desk contains two fifteen-circuit busses which terminate on the main plug-boards and are also carried through plug cords to the synchronous switches. Essential analog and forcing function points are connected to these busses so that oscillographs or synchronous switches can be connected thereto by the selector switches.

A four-wire meter bus runs from each desk throughout the length of the computer. Relay-type selectors, controlled by keyboards on each desk, cut the meter bus into any desired circuit element of the computer. At the desk, either electronic or 440-cycle vector meters can be selected on this metering bus, or the meter bus can be selected by oscillographs or synchronous switches. The latter connection gives wider coverage to these facilities, and is particularly useful in power system switching transient studies.

Each desk contains four decade resistors, four adjustable inductors and two adjustable capacitors whose terminals appear directly on the circuit elements plug-boards. These elements can be connected into the analogs the same as any of the other units but can be adjusted directly at the desk.

One synchronous switch is permanently assigned to each desk while the third switch is movable and can be plugged into either desk as desired.

This general arrangement has been evolved as a result of design calculations and experience with shielding and measurement problems during several years experience with the smaller scale computer.

3. Steady-State Forcing Functions

Physical systems for which the differential equations can be written are amenable to solution by computers. Consequently the computer nomenclature parallels that of analytical solution of the differential equation, or system of equations. For example, in the differential equation of a particular linear system, $y(p)=f(t)$, where $p=d/dt$ the right-hand side $f(t)$ is the "forcing function" of the independent variable, t. Usually, the forcing function equipment of the computer must enforce the restraint corresponding to the application of this known force. If it is desired merely to reveal the natural frequencies and damping rates the forcing function may be very simple, such as unit function. However, many of the forces to which a physical system may be subjected are complicated functions of time. Considerable flexibility is required for a computer to produce almost any desired forcing function. In general, these may be divided into steady state and transient forcing functions. The facilities provided on the new electric analog computer for steady forcing functions are the following.

Variable Frequency Units. Four electronic power sources are provided in the Westinghouse computer, six in the California Institute's computer. In each case these are operated synchronously from a single master oscillator but are separately adjustable in phase and magnitude. These sources are single phase, 0 to 50 volt, and cover the frequency range from 100 to 1,600 cycles. A unique phase angle adjustment is provided which is relatively independent of frequency, over nearly four to one frequency range. Thus, with out-of-phase exciting force applied to a system, the response as a function of frequency can be obtained by varying the oscillator without changing the phase positions of applied forces. This forcing function is shown diagrammatically in Figure 6.

The sinusoidal forcing functions for the California Institute computer are designed for 50 volts at one ampere to increase their usefulness for electric power system problems.

Constant Frequency Units. On the Westinghouse computer four 440-cycle power sources are provided similar to those used on the a-c calculating board.[16] A synchronously driven motor-generator set supplies the 440-cycle power. Each "source" consists of a phase shifter for adjusting the phase angle and a pair of oppositely rotating phase shifters for controlling magnitude. These sources are single phase, 0 to 220 volt, 0 to 3 ampere and provide for operation at a higher power level where variable frequency is not required.

Direct Current Supplies. Several d-c power supplies are available, namely lead cell storage batteries in steps up to 48 or 72 volts, heavy duty *B* batteries up to 500 volts 250/500 volt regulated power supplies, 0 to 500 mils and several others. All variable frequency power supplies, amplifiers and multipliers have integral

shielded d-c power supplies. The shielding is discussed later.

4. Transient Forcing Functions

As a majority of the transient computations are performed by repeating the transient, the forcing functions are arranged to provide this repetition. Two general forms are used.

General Arbitrary Function of the Independent Variable. Three units of this type are installed and are illustrated in Figure 5 (drum to right of desk) and in Figure 7. The voltages of 100 consecutive bars of the 200 bar commutator are separately adjustable by means of the 100 stage drum-type selector switch. The other bars are connected together for the "off" period. As a brush sweeps around, it picks off the desired function of time (the independent variable). This can be used as a voltage or converted into a current by means of the current forcing function (described later), depending upon the needs of the problem. In addition to the arbitrary voltage forcing functions mentioned before, the California Institute computer also has two phonograph-type pick-up circuits that play specially prepared records to generate any desired voltage function.

Current Type Forcing Functions. Electronic amplifiers or current regulators are provided which can force a current to follow a prescribed voltage pattern. By this device practically any forcing function which can be generated as a voltage can be converted to a current type of forcing function, if this is required for the analog used. In the California Institute computer, for example, three of these constant current generators are provided. They employ pentodes that will supply up to 50 mils through impedances up to 100,000 ohms. These can be driven from any of the voltage sources so as to provide any form of current function.

Synchronous Switch. A large variety of transient forcing functions can be produced by means of the synchronous switch used in conjunction with power sources, circuit parameters, amplifiers, and other computer elements.

The synchronous switch, shown in Figure 8, is an eight-stage-rotating drum-type switch, each stage of which is separately adjustable in phase and duration of closure. It is driven by a special synchronous induction motor usually at 600 rpm but having gears for 1,200 and 1,800 rpm. Because of its mass and the synchronous operation, the speed is very steady and a high degree of switching definition is obtained, for accurate repetition. The stages are indexed to facilitate returning readily to a previous phenomenon. Low brush drop is achieved by special alloy drums and silver–graphite brushes.

The 30-bus selector is mounted integral with the switch. When the analog points of interest are connected to these 30 busses the switch stages can readily be switched to the desired locations.

The simplest transient forcing function is, of course, simply on-off switching. Unit function can be made up by means of a low-impedance battery shorted through a resistor by a switch stage. When the switch opens each cycle, the battery voltage is applied. As one ampere can be readily commutated, a 6-ohm resistor can be used with 6-volt battery, providing six ohm effective internal impedance during the open period and zero during the closed period.

A more complex transient forcing function produced by d-c power source, oscillating circuits and synchronous switch is shown in Figure 2. The capacitors are charged during the open period through high resistance and are simultaneously discharged by closure of the switch stage to produce the desired forcing function. The currents are combined in appropriate portions of the slide wire resistor to form the forcing voltage. Independence of analog and forcing function circuits is secured by low impedance of the slide wire, and by low voltage across the slide wire compared with the oscillating forcing function circuits.

Spliced Waves. The synchronous switch also provides rich possibilities in the "splicing" of sections of waves from different sources to form a desired forcing function. A sloped front, flat topped wave is formed by using the first 20 or 30 degrees of a sine wave and switching to a battery. For studying rectifier and inverter wave shape problems the switch stages perform the periodic switching functions in the circuit normally performed by the rectifier valves. Angles of overlap and grid delay or advance can be readily controlled.

De-energizing Circuits. The de-energizing circuits are secondary or less critical forcing functions used to remove energy from the analogy during the "off" period, restoring it more quickly to the correct initial boundary conditions for reapplication of the transient phenomena. They consist generally of damping resistors applied at appropriate times by synchronous switches.

5. Analog Elements

The analog is the heart of the computer. This portion comprises all of the basic elements, resistors, inductors, capacitors, transformers, amplifiers, and multipliers. The accuracy of the computer hinges on the maintenance of high standards of accuracy. This requires linearity, permanence of calibration, and minimizing the effects of leakage and stray fields. Extensive developments have been carried on to improve the basic analog elements and to eliminate sources of error found through experience on the smaller scale computer.

High Q Inductors. Inductance coils have been developed having a Q of 100 or higher over the frequency range from 100 cycles to 1,000 cycles, and having inductance values and taps as indicated on Appendix I. It was desirable to make these inductors as small as possible as they are one of the major space consuming items of the computer. They also represent a considerable item of cost. Coppernik F laminations of five mils thickness were selected as most suitable for this application. The air gap is at the center of the core which minimizes fringing and interference between inductors. Both theoretical and experimental analyses were carried out to find the best proportions for general computer purposes.

Capacitors and Resistors. Precision capacitors and resistors were used for all of the variable units of the new computer to eliminate the necessity of bridge measurement or trimming of units used in problems requiring the higher degree of accuracy. Resistors and inductors were in general combined into R-L circuits. Each such circuit is brought to a single pair of plugs and requires a single metering relay. Either parameter can, of course, be set at zero. No problem could be foreseen requiring large numbers of both resistors and inductors, other than in this series combination.

Special Transformers. In certain mechanical problems, such as impact loaded beam for example, the analog requires the use of transformers in order to enforce the restraints between certain currents without requiring metallic interconnections of the circuits involved. These transformers should be as nearly perfect as possible; that is, they should have minimum exciting current and leakage reactance and resistance. At the same time, the size should be kept within bounds commensurate with general computer design and cost.

Figure 4. Wiring plan of Westinghouse electric analog computer (For letter symbols refer to corresponding letters in Appendix IA)

The distributed capacity between windings and from winding to ground should be as low as possible. In general, leakage reactance can be minimized by interleaving at the expense of increasing the winding-to-winding capacity so that an optimum compromise has to be developed between these two conflicting requirements. Five-mil hydrifined molybdenum permalloy bar piece laminations were selected for the cores of these transformers. The resulting units have a ratio of exciting impedance to leakage impedance of 1,400 and winding-to-winding capacitance of 400 micro-microfarads.

Time Delay Units. Time delay units are adjustable resistance-capacitance circuits used primarily on conjunction with amplifiers to simulate the time constants of various stages of control and servomechanism systems. Internal resistance of the preceding amplifier stage is included in any accurate work.

Amplifiers. Amplifiers enter extensively into the analogs; without them the field of the analog computer would be greatly restricted. Circuits can be arranged which are analogous to certain parts of the system under study. Voltages or currents may be derived from these circuits without loading them or distorting their theoretical performance and these quantities amplified in turn to provide relatively large power sources to drive other elements of the analog.

One of the problems has been the provision of shielding suitable to permit operation of the amplifier at potentials elevated from ground. This has been accomplished by a specially shielded transformer in the power supply to each individual amplifier and by other measures. The complete amplifier chassis is insulated from the supporting frame and can be used at elevated potentials when required in the analogy. One of these units is shown in Figure 9.

Multipliers. In the multiplier even more than in a simple amplifier, isolation becomes one of the major problems. Two general designs of multipliers have been adopted for the computer. One, devised by R. C. Cheek, uses a carrier signal. Figure 10 shows the carrier-type multiplier.

The second type uses a mixer-type multigrid tube. This arrangement is somewhat simpler and can be used where isolation is not required, as in the case in certain analogies. A particularly important use of the multiplier is in the provision of square law elements for representation of elements of a hydraulic problem or gas flow problem. In this case, the two inputs may of course be common and may also have a common point with the output so that all sections of the multiplier can be operated with a single chassis ground tied into one point of the analog. Even with this arrangement, it is essential to have a specially shielded input transformer for the power supply.

6. Nonlinear Functions of the Dependent Variable

In many problems it is necessary to produce nonlinear functions of the dependent variables, that is, of the currents or voltages appearing in the analog. Several

Figure 5. General view of computer installed at the California Institute of Technology

Figure 6. Variable frequency forcing function

devices have been developed to produce such functions. Diode or rectifier circuits have been built up to simulate many of the simpler functions. For example, the discontinuous current and voltage limiting circuits have been so obtained.

The California Institute computer has two elements that can generate arbitrary, single-valued functions of a dependent variable, and more are being constructed. They employ a cathode-ray oscillograph with a very short persistence screen. It is swept along one axis at a constant high frequency rate and along the other axis by the dependent variable. A mask is placed over the screen to represent the desired function and the light from the screen picked up by a photocell and amplified.

Multipliers and arbitrary functions of the dependent variable are extremely important components of the computer since they extend its application into the general field of nonlinear problems.

7. Measuring Equipment

Several types of measuring equipment are used in connection with the computer. These include cathode-ray oscillographs, cameras, harmonic analyzers, and all types of conventional a-c and d-c ammeters, voltmeters and wattmeters both indicating and recording.

Horizontal time sweeps are obtained either using the internal sweep circuits of the cathode-ray oscillograph or, where greater accuracy or longer scales are required, the use of a drum or disk type rotating film holder is used. This is driven synchronously so that by repeating the transient the equivalent of a very high writing speed can be obtained. The synchronous operation and suitable inertia also provides the required linearity of sweep.

Metering Desk. Figure 5 shows the general arrangement of instruments and controls on one of the metering desks. The oscillographs are mounted directly in the center, with their 15-bus selector switches at the right. A fixed focus camera slips over the front of the oscillograph for photographic recording of data.

The upper panel also contains voltmeter, ammeter, and wattmeter operated through electronic metering amplifiers to register these quantities over the frequency range from 30 to 2,000 cycles. At the left is the oscillator controlling the variable frequency forcing functions.

The other controls are power switches, circuit selector keys, miscellaneous selector switches, and adjustments of the desk mounted R, L, and C parameters. The vector 440-cycle meters and the phase shifter for controlling the reference current are mounted on a sloping panel on one desk of the Westinghouse computer.

Portable Measuring Equipment. Practically all types of indicating and recording instruments used in general power system work can also be used in special problems to make measurements on the computer. More frequently used devices are made part of the computer, whereas others are shared with other laboratories. A few examples will be mentioned.

Harmonic Analyzer. In rectifier and inverter problems the synchronous switches are used as mechanical rectifiers, the angle corresponding to overlap and ignitor delay or advance being readily adjustable. The resulting wave shapes are analyzed by harmonic analyzer, just as they would be on an actual system. This instrument is also useful in the steady-state saturation problems such as ferroresonance.

Wire and Tape Recorders. The wire recorder may of course be used for storing solutions of a noncritical character, or solutions in which wave shape, or damping rates are of chief concern. A recording of from a few seconds to a minute of a repeated wave form would usually be sufficient for later examination.

The transient tape recorder, operating with a short continuous belt of recording tape, makes it possible to play back repetitively a "single shot" transient solution. This technique is useful when restoration of the initial boundary conditions is difficult with the repetitive method.

Both the wire and tape recorders offer possibilities as forcing functions as well. Some development work has been carried on along this line. However, other methods appear more direct for the present.

8. Shielding

The difficulties of using a cathode-ray oscillograph at elevated potentials are well known. The possibilities of cross talk or pickup at audio frequencies in an extensive computer operating at these frequencies are also quite apparent. Consequently a large part of the development of equipment and techniques required to insure accuracy must be directed toward elimination of these undesirable stray effects.

A complete résumé of the shielding considerations is entirely beyond the scope of this paper. The following discussion will serve to outline the general problem and indicate the nature of the solution.

Stray effects are of two general types, namely, those which introduce voltages into the analog, and those which change the value of parameters. In general these effects are resistive, inductive, and capacitive. All are important in certain cases.

A stray voltage of 1 per cent induced into a circuit may be amplified 100 times if it happens to be at the resonant frequency of an L-C circuit having a Q of 100. A stray capacitance which appears utterly unimportant at the working frequency may oscillate with a coil in a system of high amplification, obscuring the solution.

A leakage resistance 100 times any of the analog impedances may be thought unimportant. If it terminates in an extraneous voltage source 100 times as large as the voltage in that part of the analog, the stray current may be equal to the working current in the analog.

Extreme cases have been cited which would result in gross errors or nonoperation. However, shielding methods and techniques have been developed which keep these effects well within the limits necessary for good engineering accuracy. This has been accomplished by capacitive and magnetic shielding, by design arrange-

ments that eliminate the sorts of leakage paths cited, and by minimizing capacitance to ground or between wires or devices.

For example lead capacitances have been reduced approximately ten-to-one by the use of spaced bare wire instead of bundled conductors. Inductance coils are arranged with the gap in the center leg, thereby minimizing stray fluxes and effectively shielding the coil from extraneous fields. Optimum use has been made by the shielding possibilities of the steel enclosures.

9. Combined Functions of A-C Calculating Board and Analog Computer

The Westinghouse analog computer is located adjacent to the a-c calculating board and interconnections are provided to permit the facilities of either calculator to be used in connection with the other. This procedure greatly increases the utility of both facilities. The a-c calculating board includes 200 resistor-reactor units, 48 capacitor units, 18 low-loss reactors, 78 transformers and 18 440-cycle powers sources. All of these units are available at certain times for extensive problems on the analog computer. This arrangement has been in use for several years with the small computer. It has proven most advantageous, particularly for power system switching problems and other electrical transients.

The Q of the a-c calculator coils is not sufficiently high for many of the mechanical system transient problems. It is approximately 25 at 440 cycles compared with 100 or higher over the full 100 to 1,000 cycle range for the coils associated with the analog computer. However a Q of 25 is quite adequate for most electric circuit problems and many others.

The interchange operates in both directions. The four 440-cycle power sources of the analog computer together with the 144 reactor and resistor-reactor units, the 124 capacitor units and 56 transformer units can be used at certain times in connection with the a-c calculating board problems. Sixty-eight interchange circuits are provided initially to take advantage of this flexibility.

Application and Conclusions

The list of problems given in Appendix II illustrates the general field of application of the electric analog computer. However, as titled, this list is purely suggestive rather than complete. The list grows almost daily as one new problem after another is found to be amenable to study on the computer. The capabilities of the computer suggest other problems of importance that can be solved. The urgent need for solutions of still other problems suggest developments or improvements that permit solving those problems and which extend the application of the computer into new fields.

The goal in this development has been the production of a very flexible general purpose computer, one which would anticipate most of the requirements of elements and connections for analog solutions of the problems listed in Appendix II. This has required elements to simulate all the terms occurring in the differential equations of the systems to be studied. Linear circuit elements and amplifiers represent all the constant coefficients. Multipliers provide for multiplying variables. Arbitrary functions of both independent and dependent variables are provided. Accuracy depends on the problem being solved. Generally speaking, acceptable engineering accuracy of one-to-five per cent is secured for the type of problems being solved. The parameters can usually be set more closely than the data on the physical system is known, and the results are therefore nearly as accurate as the available data could produce.

The computer described has been

evolved as a result of design calculations. coupled with experience obtained during several years operation of a smaller scale computer. In spite of its limitations a wealth of useful data has been obtained from the small scale computer. With the enlarged facilities, the improved shielding, the reduction of stray effects, the greater accuracy, and the newly developed components, the horizon of the new computer has been greatly expanded.

Appendix I

A. Basic Elements of Westinghouse Electric Corporation Analog Computer*

A. Seven Passive Circuit Elements Cabinets

1. 100 high Q inductors—0 to 0.75 henry in 0.001-henry steps.
2. 20 high Q inductors—0 to 1.5 henry in 0.1-henry steps.
3. 20 high Q inductors—0 to 0.75 henry in 0.05-henry steps.
4. 80 resistors—0 to 8,000 ohms in 2-ohm steps.
5. 10 resistors—0 to 111,000 ohms in 200-ohm steps.
6. 60 capacitors—0 to 1.1 microfarad in 0.01 microfarad steps.
7. 40 capacitors—0 to 4.1 microfarad in 0.01 microfarad steps.
8. 24 capacitors—10, 20, 40, or 80 microfarad fixed.
9. 55 special transformers.

B. Five Plug-boards

1. Plug leads for all elements of the seven circuit element cabinets, three forcing function cabinets, and a-c calculating board interconnections.
2. Receptacle patch boards for circuit element connections, and terminations for main busses, amplifiers, multipliers, analog selector busses and relays to development area.

C. Forcing Function Cabinets

1. Four sinusoidal variable frequency and phase position voltage sources (0 to 50 volts).
2. Two separate square wave voltage sources (0 to 12 volts, or one 24-volt source in 2-volt steps).
3. Three arbitrary voltage sources (maximum 50 volts, one ohm).
4. Two arbitrary current sources (controllable from any voltage source).

D. Two Metering Desks—Each Desk

1. Three meters for metering sinusoidal audio frequency current, voltage, power.
2. Two cathode-ray oscillographs for transient solutions.
3. One 4-wire metering circuit (and selector system) for metering all passive circuit elements and source forcing functions.
4. Two 15-circuit analog selector busses.
5. Seven adjustable R, L, C circuits with terminations on plug-boards (4 R, 1 L, 2 C).
6. Master oscillator for sinusoidal variable frequency forcing functions.
7. Slide wire (6 slide) for combinations of forcing functions.

One Desk

8. Vector ammeter and voltmeter for 440-cycle metering.

E. Amplifier—Multiplier Cabinets (portable)

1. Twenty amplifier units, each having an RC time-delay circuit for servo problems.
2. Six multipliers with isolated inputs. (Part under construction.)

F. Arbitrary Functions of Dependent Variable (portable)

1. Two voltage limiters.
2. Two arbitrary function devices (single valued.)

G. Synchronous Switches

1. Three 8-stage synchronous switches (one portable).
2. Integral 16-circuit selectors for analog busses.

H. Constant Frequency Forcing Function

1. Four 440-cycle 250-volt 3-ampere sources adjustable in phase and magnitude. Control local or remote from a-c calculating board.

B. Basic Elements of the California Institute of Technology Electric Analog Computer†

A. Ten Passive Circuit Elements Cabinets

1. 100 high Q inductors—0 to 0.90 henry in 0.001-henry steps.
2. 20 high Q inductors—0 to 1.50 henrys in 0.01-henry steps.
3. 100 resistors—0 to 6,000 ohms in 2-ohm steps.
4. 20 resistors—0 to 150,000 ohms in 200-ohm steps.
5. 60 capacitors—0 to 1.0 microfarad in 0.01-microfarad steps.
6. 40 capacitors—0 to 5.0 microfarad in 0.01-microfarad steps.
7. 10 capacitors—0 to 100 microfarad in 10-microfarad steps.
8. 25 special transformers.‡

B. Five Plug-boards

1. Plug-boards for all elements of two circuit elements cabinets.
2. Receptacle patch board for 500 element connections and 25 main busses.

C. One Forcing Functions Cabinet

1. Six sinusoidal variable frequency and phase position voltage sources (0 to 50 volts, one ampere, one ohm).
2. Six separate square wave voltage sources (0 to 12 volts, or one 72 volt source in 2-volt steps).
3. Four arbitrary voltage sources (maximum 50 volts, one ohm).
4. Four arbitrary current sources (controllable from any voltage source).

D. One Metering Desk

1. Three dynamometer type meters for metering sinusoidal current and voltage.

* See schematic diagram of Figure 3a.

† See schematic diagram of Figure 3 b.

‡ Additional elements are contemplated. Table lists only elements of computer in its present operating form.

2. Two cathode-ray oscillographs for transient solution (current, voltage, or charge).

3. One 3-wire metering circuit (and selector system) for metering all passive circuit elements and source forcing functions.

4. One manual metering selector circuit for 16 of 25 main busses.

5. Circuits for connecting eight synchronous switches to any of 16 main busses.

E. Amplifier Cabinets (portable)

1. Five negative gain (0 to 50) d-c amplifiers (one ohm impedance), each having an *RC* time delay circuit for servo problems.

2. Ten positive gain (0 to 500) d-c amplifiers with isolated input and one ohm output impedance.‡

F. Multiplier Cabinets (portable)

1. Three multipliers with isolated inputs and one ohm output impedance‡ (five more are being built).

G. Arbitrary Functions of Dependent Variable (portable)

1. Three voltage limiters.
2. Two current limiters.
3. Two perfectly arbitrary function devices‡ (five more to be built).

Appendix II. Suggested List of Engineering Problems Suited to the Electric Analog Computer

Electric Circuits

The computer includes many of the facilities of an a-c or d-c network analyzer. As an a-c analyzer it can handle steady-state problems of importance to electrical utilities. These are briefly listed as follows:

1. Steady-state power flow problems.

2. System short-circuit calculations for relay and circuit-breaker application.

3. System stability problems.

As a d-c calculating board the computer can handle:

4. Distribution circuit analysis.

5. D-c circuit analysis.

The transient facilities will enable it to handle the following important system transient problems.

6. Switching surge and arcing ground studies on power systems.

7. Electronic rectifier and inverter circuit analysis.

8. Transients in other types of circuits.

More general types of circuits than can be analyzed include the following:

9. Aircraft electrical circuit analysis.

10. Ship electrical circuit analysis.

11. Analysis of dielectric and induction heating circuits.

12. Solution of rotating machine equations.

13. Certain special industrial circuit analysis.

14. Plugging steel mill motors; combined electro-mechanical problem.

15. Switching surges in rotating machine windings and surge voltage distribution.

16. Analysis of surge voltage distribution in transformer windings.

17. Dielectric field problems encountered in insulation design.

18. Analysis of automatic load control circuits for turbine generators—also related to servomechanism classification.

The various laboratory facilities will provide a much more ready method than hitherto available for certain types of general analysis:

19. Analysis by frequency-impedance and frequency-reactance curves.

20. Conversion of circuits to other equivalent circuits such as determination of *ABCD* constants.

21. Determination of equivalent circuits from test data.

The multipliers permit the solution of certain important rotating machine equations, certain of which are listed under servomechanisms. The elements for representing arbitrary functions of the dependent variable of course extend the computer's usefulness in the general nonlinear field and enable the solution of such important electrical problems as ferro-resonance, electronic and rotating machine performance under saturated conditions.

Applied Mechanics

One of the largest fields of application for such an analyzer has been found to be in the field of mechanics. Vibration analysis has hitherto been entirely inadequate in most design departments. With the computer many of the analyses can be made in dimensionless form suitable for quite general applications. Examples of such studies that have been made are the following:

22. Electronic tube packaging and chassis shock analysis.

23. Vibration test table analysis.

The following is a partial list of typical lumped constants vibration problems:

24. A-c turbine generator short-circuit torques.

25. D-c generator short-circuit torques.

26. Steel mill plugging torques.

27. Vibratory analysis of ship's drives.

28. Gas and diesel engine vibratory analysis.

29. Problems of motor starting and acceleration through resonance frequencies of mechanical systems.

30. Analysis of certain kinds of timing mechanisms.

31. Determination of damping factors and other parameters by correlation with test data.

32. Analysis of effect of imperfections in large gear teeth.

33. Complete analysis of regulated rotating systems (see servomechanisms).

There are similar types of mechanical systems involving translational motion, such as:

34. Shock problems such as encountered in naval ship equipment when guns are firing.

35. Analysis of mechanical wave filters.

Methods of analysis have been developed for all forms of lumped constants systems undergoing any form of motion, or combined translational and rotational motion. Such problems can readily be handled for all systems as long as the angular motion is relatively small:

36. Rail car truck stability.

37. Radial aircraft engine vibration analysis.

38. Aircraft generator vibration analysis.

39. Vibration testing devices for aircraft.

40. Gyroscope analysis.

41. Analysis of vehicle ridability.

Beam Vibration Problems

This covers a very broad field of important design problems, many too complex for analysis by any other known means. The basic analogies have been developed for the general beam under all forms of support and loading. Multiple beams connected through various forms of lumped constant elements can also be analyzed.

42. Static loading of beams.

43. Dynamic beam loading and vibration.

44. Determination of critical shear stresses and bending moments.

45. Determination of critical frequencies of beams.

46. Straight and curved beams.

47. Multiple beam systems such as shafts with rotating inertias mounted through bearings to frames composed of beams.

48. General combined beam and lumped mechanical constant systems.

49. Air frame flutter problems (combined torsion and bending).

50. General analysis of methods of acceleration damping (air frames).

51. Dynamic and pulse studies of steam turbine blades.

For the latter three items the number of elements available in the initial analyzer installation will probably not be sufficient for some of the more complex problems of importance to industry. However, valuable basic studies can be made on some of the simpler systems. These may permit generalization or show that addition to the number of board elements is justified. This statement also applies to several of the following items:

52. Beam shock problems, such as landing shocks on air frames.

53. Strain analysis of sucker-rod oil well pump systems.

54. Oscillations in suspension bridges.

55. Beams on elastic foundations.

56. Analysis of nonsymmetrical rotors on shafts.

Self-Induced Mechanical Oscillations

57. Airplane structure flutter.

58. Systems with instability induced by oil lubricated bearings, and so forth.

59. Car shimmy, and so forth.

60. Rail car truck stability.

61. Oscillations in closed surge tanks (also hydraulic).

General Theory of Elastic Stability

62. Stability of shear webbs of beams (plate girders).

63. Buckling of columns under end loading.

Thermodynamics

Transient and steady-state heat flow problems are another important field of application for the Computer. Most of these will also be problems involving one or more continuous conducting media. However, it has been found that a great many of such problems can be adequately handled with the number of elements being considered here.

64. General analysis of both steady-state and transient heat flow problems. Of particular general importance would be analysis correlated with test data to determine certain coefficients of heat transmission and surface conduction.

65. General studies of economic thickness of thermal insulation for intermittent operation.

66. Thermal ratings and temperature studies of various machines under intermittent operation.

67. Temperature distribution in electrical coils.

68. Ventilation design problems—rotating and static machine design.

69. Effect of through metal in insulated walls.

70. Temperature gradients in lubricating films and bearing shells.

71. Temperature distribution and heat flow in gas turbines and jet engines.

72. Transient heating of turbines.

73. Transient heating in motor and generator.

74. Damper rings and bars.

There are several other distributed constants media to which the method of electrical analogy and the analyzer can have important application. These include electric current distribution in large electrical conducting media, hydraulic problems, and electromagnetic wave propagation. Hydraulic problems include the following:

75. Penstock problems.

76. Water hammer.

77. Valve stability.

Combined Physical Systems Including Servomechanism

There are several types of important engineering problems involving several interrelated physical systems. Most of these consist of electrical, mechanical, thermal, and hydraulic elements. Numerous among these are process control systems and the most important types come under the category of servomechanisms. Many of these linear systems are well suited to general analysis in dimensionless form:

78. Transient heating of turbines.

79. Transient heating in motor and generator damper rings and bars.

Angle-Position Controllers

80. Gun controllers.

81. Tank turret controllers.

82. Rail car bank controller.

83. Airplane stabilizers—gyro pilots.

84. Guided missiles.

85. Elevator control systems, and many others.

Voltage Regulators

86. Complete generator system analysis.

87. Rotating exciters.

88. Electronic exciters.

89. Rototrol systems.

Speed Controllers

90. Rolling mill equipment.

91. Generator governors.

92. Analysis of complete wind tunnel drives.

Progress Report on AIEE-ASME Standard Large 3,000-RPM Turbine Generators

S. H. MORTENSEN
FELLOW AIEE

J. B. McCLURE
MEMBER AIEE

C. M. LAFFOON
FELLOW AIEE

THE report of the joint AIEE-ASME committee on proposed preferred standards for large 3,600-rpm 3-phase 60-cycle condensing turbine generators was made available to the AIEE standards committee in October, 1944. It was later presented under the sponsorship of the power generation committee at the 1945 AIEE winter meeting in New York, N. Y.

AIEE Standard 601 covering the joint AIEE-ASME preferred standards for large 3,600-rpm condensing steam turbine generators was approved by council, ASME, February 23, 1945 and by the board of directors, AIEE, February 27, 1945. The companion AIEE Standard 602 covering standard specification data for generators for large 3,600-rpm condensing steam turbines was approved by the board of directors, AIEE, February 27, 1945.

Table I gives the ratings and characteristics of the six units covered by the preferred standards.

Approximately three years' time has elapsed since the standards were officially adopted for trial use, and it is now appropriate that a review be made to check the progress made by the manufacturers in developing and building the units, and the degree of acceptance of the program by the electric utility industry. This progress report is restricted to the scope of the AIEE portion of the joint committee, although the data submitted covers the complete turbine-generator units. The adoption of the standards came at the time industry was in the process of converting from war to a peace-time program. The development of the six new standard turbine-generator units necessitated the making of engineering designs, manufacturing and customer approval drawings, manufacturing tools and assembly equipment. The drafting load involved in producing drawings for the generators only, represented three to four thousand man-days work. The manufacturers were further faced with a shortage of both experienced and inexperienced draftsmen, design and manufacturing engineers, and hampered by a large flood of orders, strikes and other disturbing economic conditions.

Table I. Preferred Standards for Large 3,600-Rpm, 3-Phase, 60-Cycle Condensing Steam Turbine Generator

	Air-Cooled Generator	Hydrogen-Cooled Generator Rated for 0.5 Pound Per Square Inch Gauge Hydrogen Pressure				
Turbine-generator rating, kilowatts	11,500	15,000	20,000	30,000	40,000	60,000
Turbine capability, kilowatts	12,650	16,500	22,000	33,000	44,000	66,000
Generator rating, kilovolt-amperes	13,529	17,647	23,529	35,294	47,058	70,588
Power factor	0.85	0.85	0.85	0.85	0.85	0.85
Short circuit ratio	0.8	0.8	0.8	0.8	0.8	0.8
		Hydrogen-Cooled Generator Operated at 15 Pounds Per Square Inch Gauge Hydrogen Pressure				
Generator capability at 0.85 power factor, kilovolt-ampere			27,058	40,588	54,117	81,176

Table II. Customer Orders Obtained by the General Electric Company for Preferred Standard Ratings up to December 1, 1947

Kilowatt Rating	Number of Units	Total Kilowatt Capacity
11,500	4	46,000
15,000	0	
20,000	6	120,000
30,000	9	270,000
40,000	20	800,000
60,000	21	1,260,000
Total	60	2,496,000*

* The number of units and total kilowatt capacity represents approximately one-third of the General Electric turbine generator business in sizes of 10,000 kw and larger.

There was an increasing need by the utility industry for the purchase and delivery of more and more steam driven turbine-generator units to meet rapidly increasing loads. Both manufacturer and purchaser were faced with the desire on one hand to use the old type units which were already developed and defer the development of the new units, and on the other hand, to carry through both programs simultaneously. All manufacturers recognized that in many other respects this was an ideal time to introduce the new standard line and that any appreciable delay in the development of the new ratings would seriously jeopardize the over-all acceptance of the program, and thus it was decided to develop the new standard ratings as quickly as possible. At present there are four manufacturing companies in the United States which are interested in building these standard units. Three are concerned with all ratings and one is concerned only with the smaller ratings. The following tables

Paper 48-110, recommended by the AIEE power generation committee and approved by the AIEE technical program committee for presentation at the AIEE Great Lakes District meeting, Des Moines, Iowa, April 1–3, 1948. Manuscript submitted December 16, 1947; made available for printing February 20, 1948.

S. H. MORTENSEN is chief electrical engineer, Allis-Chalmers Manufacturing Company, Milwaukee, Wis., J. B. McCLURE is with the central station engineering department, General Electric Company, Schenectady, N. Y., and C. M. LAFFOON is manager, a-c generator engineering department with Westinghouse Electric Corporation, East Pittsburgh, Pa.

Table III. Customer Orders Obtained by Westinghouse Electric Corporation for Preferred Standard Ratings up to December 1, 1947

Kilowatt Rating	Number of Units	Total Kilowatt Capacity
11,500	1	11,500
15,000	0	
20,000	3	60,000
30,000	23	690,000
40,000	10	400,000
60,000	19	1,140,000
Total	56	2,301,500*

* The total kilowatt capacity represents approximately 48 per cent of the Westinghouse Electric Corporation's turbine generator business in sizes of 10,000 kw and larger.

Table IV. Customer Orders Obtained by Allis-Chalmers Company for Preferred Standard Ratings up to December 1, 1947

Kilowatt Rating	Number of Units	Total Kilowatt Capacity
11,500	2	23,000
15,000		
20,000	5	100,000
30,000	2	60,000
40,000	7	280,000
60,000	0	
Total	16	463,000*

* This represents approximately 40 to 50 per cent of Allis-Chalmers turbine generator business under construction in sizes of 10 kw and above.

In terms of machines in the same size range, the percentage of standardized units is somewhat higher, and has been steadily increasing. During the second half of 1947 about 75 per cent of the units sold within this band were of the standardized design.

Table V. Customer Orders Obtained by the Elliott Company for Preferred Standard Ratings up to December 1, 1947

Kilowatt Rating	Number of Units	Total Kilowatt Capacity
11,500	1	11,500
15,000	0	
20,000	0	
30,000	0	
40,000	0	
60,000	0	
Total	1	11,500*

* The total kilowatt capacity represents approximately 10 per cent of the Elliott turbine generator business in sizes of 10,000 kw and larger.

Table VI. Customer Orders Obtained by All Manufacturing Companies for Preferred Standard Ratings up to December 1, 1947

Kilowatt Rating	Elliott Company, Kilowatts	Allis-Chalmers Manufacturing Company, Kilowatts	Westinghouse Electric Corporation, Kilowatts	General Electric Company, Kilowatts	Total Kilowatts
11,500	11,500	23,000	11,500	46,000	92,000
15,000					
20,000		100,000	60,000	120,000	280,000
30,000		60,000	690,000	270,000	1,020,000
40,000		280,000	400,000	800,000	1,480,000
60,000			1,140,000	1,260,000	2,400,000
Total	11,500	463,000	2,301,500	2,496,000	5,272,000

show the progress made by the different manufacturing companies and the purchaser acceptance of the new standard line.

Several of the new line units have been built and shipped and are now either in operation or being erected. On the basis of the data and the general situation associated with the production of the new standard line, the following observations and conclusions can be made.

1. All of the standard line units are now available with the exception of the 15,000 kw rating.

2. The purchaser acceptance has been wide, and the number of units and total kilovolt-amperes now on order represent 35 to 40 per cent of the total turbine generator business for units of 10,000 kw rating and above.

3. In 1948 and thereafter, it is anticipated that orders placed for new units will be almost exclusively of the new standard line for the range of ratings covered by this line. It is expected that this will represent approximately 50 per cent of the current turbine-generator business in that period.

4. With the development of the standard line practically complete, the manufacturer can furnish outline and customer approval drawings at the time the negotiation proposals are presented. After the purchase order is placed, both the manufacturer and the purchaser can place orders immediately for manufacturing and construction materials. The purchaser is thus definitely assured of a better product, at reduced cost, and with shorter deliveries.

From comments and suggestions received from both purchaser and manufacturer groups, it is recommended that the existing AIEE committee again become active and consider the following items:

1. Reconsider the 15,000 kw unit and decide whether or not this rating should be designed for hydrogen cooling and have the same characteristics as the four larger ratings.

2. Review the standard specification data for generators for large 3,600-rpm condensing steam turbines for major changes, modifications, and additions.

3. Consider the advisability of standardizing the next larger 3,600-rpm hydrogen cooled unit which is being purchased in appreciable numbers for ratings of 80,000 and 90,000 kw and appropriate power factor and short circuit ratio values.

Discussion

B. H. Smith (Electric Machinery Manufacturing Company, Minneapolis, Minn.): The report mentions calling the committee to discuss suggested changes in the published standards. I would like to ask what changes have been suggested in the generator characteristics.

Frank V. Smith (Sargent and Lundy, Chicago, Ill.): The authors have done a service to the industry by assembling this material on the progress of standardization in large turbine generators. The data show that the standards have been very well received and their greater use should result in improvement in simplification of drawing procedure, economic advantages and improvement in deliveries.

Some comments might be made on the last paragraph of the paper relating to the present situation, in connection with these standards.

Both the AIEE and ASME groups of the joint committee have become active during the last few months, in order to review the points outlined by the authors and also additional items. The status at the present time is the following:

1. With regard to the 15,000 kw unit, the joint committee favors a change from air cooling to hydrogen cooling. It was guided in this decision by the advantages in reduction in losses, increased cleanliness, expected longer life and greater reactive kilovolt-ampere capacity with higher hydrogen pressures.

2. Consideration is being given to a corresponding change in the case of 11,500 kw unit. The situation here, however, is somewhat different in that an appreciable number of standard air-cooled machines have been built. Further, this rating of machine is used to a greater extent in industrial applications, rather than central station applications where the personnel is not as familiar with the problems of hydrogen equipment. At the same time, the same advantages of hydrogen cooling would be obtained as with the larger machines, and there is the feeling that the operators would

find no great difficulty in becoming familiar with the equipment. Inquiries are being made to sections of the industry to determine the sentiment on this point and discussions from members of the Institute would be welcome.

3. Serious study is being made on the possibility of a standard machine larger than 60,000 kw but this work is as yet in the preliminary stages.

The committee would be very glad indeed to have comments from operating engineers on all phases of turbine generator standardization both with regard to the proposed extension of the standards, and also with regard to minor or major modifications that might be considered worthwhile in the standards as they exist.

Balanced Fractional-Slot Wave Windings

M. M. LIWSCHITZ
MEMBER AIEE

THE a-c wave windings which are used most frequently in wound rotors of induction motors are "modified" d-c wave windings whose winding pitch is changed after each p* winding elements. These modified wave windings are balanced, but they can be applied to integral-slot and (integral+1/2)-slot windings only. The standard d-c wave winding is not used for wound rotors of induction motors for it is seldom balanced. The aim of this paper is to give a method of laying out balanced wave windings for any fractional number of slots per pole per phase for which the fractional-slot lap winding is balanced. For this purpose, the usual chart method of investigating fractional slot windings is to be abandoned and the slot star of the winding used instead.[1]

The Slot Star and the Winding Pitch

If the number of slots per pole per phase is written in the form

$$q=\frac{N}{\beta} \tag{1}$$

where N and β have no common divisor, β is the number of poles in a repeatable group of the winding, and N the number of slots per phase per repeatable group. $2p/\beta$ is the number of repeatable groups.

The slot star shows the position of the slots in the magnetic field. There are as many vectors in the slot star as there are slots in a repeatable group, that is, mN, and there are as many coinciding slot stars as there are repeatable groups. Figure 1 shows the slot star of a 3-phase winding with $q=1-4/5$. For this winding, $N=9$, and the number of vectors in the slot star is $3\times 9=27$. Two adjacent slots are not represented in the slot star by two adjacent vectors, but between two adjacent slots lie $(\beta-1)$ other vectors. (In Figure 1, $5-1=4$.) This is due to the fact that the fractional-slot winding creeps in the magnetic field and the angle between two adjacent vectors is, therefore, smaller than that between two adjacent slots. The difference between two slots which correspond to two adjacent vectors is

$$d=\frac{mNP+1}{\beta} \tag{2}$$

where P is the smallest integer which makes d an integer. For the winding of Figure 1, where $m=3$, $N=9$, and $\beta=5$,

$$d=\frac{3\times 9\times P+1}{5}=11 \text{ where } P=2$$

Corresponding to this value of d, the vectors follow the series

$$1,\ 1+11=12,\ 12+11=23,$$
$$23+11=34-3\times N=7,\ 7+11=18\ldots.$$

Because the slot star contains $mN=27$ slots, this quantity is to be subtracted when a term of the series becomes larger than 27.

The maximum distribution factor of the main wave is obtained for the winding, if the slots assigned to each phase lie as close together as possible, for example, if in Figure 1, the first $N=9$ slots are assigned to phase A, the following nine slots to phase C, and the last nine slots to phase B. This is the usual way to assign the slots to the three phases in fractional-slot lap windings.

Figure 1. Slot star of a 3-phase winding with $q=1-4/5$

In order to determine the slots which are to be assigned in this manner to the three phases, it is not necessary to draw the slot star. The d-series does this in a simpler way. This series yields, for example, for phase A of the winding considered in Figure 1 the slots,

1 12 23 7 18 2 13 24 8

This is in accordance with the slot star. Arranging the nine slots in the sequence in which they follow in the machine, that is,

1–2 7–8 12–13 18 23–24

four groups with two slots each and one group with one slot are obtained.

With two conductors per slot, one in each layer, the slot star shows the position in the magnetic field of not only the slots,

---

Paper 48-152, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28–30, 1948. Manuscript submitted October 21, 1947; made available for printing February 27, 1948.

M. M. Liwschitz is a professor with the Polytechnic Institute of Brooklyn, Brooklyn, N. Y., and also is connected with the Westinghouse Electric Corporation, East Pittsburgh, Pa., as consulting engineer.

*See List of Symbols.

but of the upper or lower conductors as well.

Making, at first, the assumption that there are only two conductors per slot, the nine figures obtained from the d-series for phase A represent the nine upper conductors assigned in each repeatable group to this phase. In the lap winding two consecutive upper conductors lie in adjacent slots, for example, in slots 1 and 2, 7 and 8, and so forth. In order to obtain maximum distribution for the main wave in the wave winding, the same conductors must be assigned to the phases as in the lap winding, yet in the wave winding two consecutive upper conductors must lie not in adjacent slots, but y slot pitches apart. The upper or the lower conductors of the wave winding must follow the y-series.

$$1,\ 1+y,\ 1+2y,\ 1+3y \ldots\ldots$$

The problem of laying out a balanced wave winding consists in the co-ordinating of the d-series and y-series of the winding.

Layout of A Balanced Wave Winding

Because the number of slots in two poles, $(2mN)/\beta$ is a fractional number, the winding pitch must be

$$y=\frac{2mN+a}{\beta} \tag{3}$$

where a is the smallest integer which makes y an integer (a can be positive as well as negative).

The magnitude of a determines the kind of co-ordination of the d-series and y-series and through it the number of winding parts in each phase. The sign of a determines whether the winding goes in the same direction as the numbering of the slots or opposite to it

Due to the fact that each p coils of the wave winding go around the whole rotor or stator, the consideration of the wave winding cannot be limited to one repeatable group, but must comprise all $2p/\beta$ repeatable groups. This means that in the case of the wave winding, all $2p/\beta$ slot stars or, what is the same, all $2p/\beta$ d-series must be considered simultaneously. If the slots of the machine are numbered by consecutive digits, the slot star of the second repeatable group is obtained from the slot star of the first repeatable group by adding the quantity mN to all numbers of the latter slot star. The same applies to the d-series. When the first d-series is set up, the second d-series is obtained by adding mN to the numbers of the first d-series, the third by adding mN to the numbers of the second d-series, and so forth. The $2p/\beta$ d-series represent the upper or lower conductors of the whole winding.

The vectors of the $2p/\beta$ slot stars coincide, that is, if the d-series are written one above the other, the $2p/\beta$ conductors which lie in the same column are in phase and can be substituted one for the other. This fact makes it possible to lay out balanced wave windings.

The method of laying out a balanced wave winding and the influence of the magnitude and sign of a (equation 3) will be demonstrated by several examples:

(*a*) $a=+1$.

It follows from equations 2 and 3 that in this case $y=d$, that is, the y-series and d-series are identical. Therefore, the winding can be made up by using the consecutive vectors of the slot-star or their in-phase vectors or, what is the same, by using the consecutive numbers of the $2p/\beta$ d-series. The 3-phase winding shown in Figure 1 is an example for $a=+1$. For this winding, d has been determined to be 11. From equation 3

$$y=\frac{6\times 9+a}{5}=11=d \text{ with } a=+1$$

Assuming that the machine has ten poles, there are $10/5=2$ d-series. They are for phase A

$$\left.\begin{array}{ccccccccc} 1 & 12 & 23 & 7 & 18 & 2 & 13 & 24 & 8 \\ 28 & 39 & 50 & 34 & 45 & 29 & 40 & 51 & 35 \end{array}\right\} d\text{-series}$$

Hence, the two y-series, that is, the 2 winding parts of phase A are

$$\left.\begin{array}{ccccccccc} 1 & 12 & 23 & 34 & 45 & 2 & 13 & 24 & 35 \\ 28 & 39 & 50 & 7 & 18 & 29 & 40 & 51 & 8 \end{array}\right\} y\text{-series}$$

The winding goes clockwise, with the numbering of the slots.

(*b*) $a=-1$.

In this case, $y=mN-d$ and the y-series will be found in the slot star or d-series running opposite to the numbering of the slots. Consider a 10-pole 3-phase winding with $q=2^1/_6$. For this winding $N=11$, $\beta=5$, and

$$d=\frac{33\times P+1}{5}=20$$

$$y=\frac{6\times 11+a}{5}=13 \text{ with } a=-1$$

$$y=mN-d=33-20=13$$

The d-series of this winding for phase A are

1	21	8	28	15	2	22	9	29	16	3
34	54	41	61	48	35	55	42	62	49	36

Considering these series, the y-series is found going from the right to the left. For example, in the first d-series

$$3,\ 3+13=16,\ 16+13=29,$$
$$29+13=42-mN=9\ldots.$$

This winding goes counter clockwise. The two y-series, that is, the two winding parts of phase A are

1	54	41	28	15	2	55	42	29	16	3
34	21	8	61	48	35	22	9	62	49	36

(*c*) $a=+2$.

In this case, $y=2d$ and the y-series is represented by the alternate numbers of the d-series. This leads to twice as many parts in each phase as when $a=+1$. The winding goes clockwise for a is positive. Consider a 10-pole 3-phase winding with $q=3^3/_5$. For this winding, $N=18$, $\beta=5$, and

$$d=\frac{54\times P+1}{5}=11$$

$$y=\frac{6\times 18+a}{5}=22 \text{ with } a=+2$$

$$y=2d=22$$

The d-series of this winding for phase A are

1	12	23	34	45	2	13	24	35	46	3	14	25	36	47	4	15	26	d-series
55	66	77	88	99	56	67	78	89	100	57	68	79	90	101	58	69	80	

The four y-series, that is, the four winding parts of phase A are

1	23	45	67	89	3	25	47	69
12	34	56	78	100	14	36	58	80
55	77	99	13	35	57	79	101	15
66	88	2	24	46	68	90	4	26

The first and second winding parts are not in phase and must be connected in series. The same applies to the third and fourth winding parts. When N is odd, the first and third winding parts have one coil more than the second and fourth winding parts.

(*d*) $a=-2$ *and* $a>2$.

In the case $a=-2$, $y=2(mN-d)$ and the y-series is represented, as in the case $a=+2$, by the alternate numbers of the d-series. However, the y-series runs opposite to the d-series similar to the case $a=-1$, and the winding goes counter clockwise. When $a>2$ the number of parts of each phase is $(2p/\beta)\times a$. Again, the winding goes clockwise, when a is positive, and counter clockwise, when a is negative.

The assumption has been made that there are only two conductors per slot. If the number of conductors per slot is larger than two, the winding can be considered as one having a number of slots equal to the actual number of slots times the number of conductors per slot per layer. This makes each slot have only two conductors and the rules for laying out the wave winding previously given can be applied.

The fractional slot wave windings explained before are balanced and have the same magnetomotive force curves as the corresponding fractional slot lap windings, because the same slots are assigned to the three phases in both windings. Also, the maximum possible number of parallel paths

is the same as for the fractional slot lap windings. Comparing the wave windings explained here with the "modified" d-c windings, the latter have only two winding parts per phase, independently of the number of poles. The number of winding parts per phase of the windings considered here depends upon the number of slots and the magnitude of a. On the other hand, the modified d-c windings have abnormal front pitches after each p coils, while in the windings just described, all coils are equal. The manufacturing of the latter windings is, therefore, less expensive than that of the modified d-c windings, except in the cases when a is large.

The designer who uses the integral slot or (integer + 1/2) slot wave winding may obtain a less expensive winding by using the layout methods previously described.

List of Symbols

a = smallest integer which makes y an integer
d = difference between two slots which correspond to two adjacent vectors of the slot star
m = number of phases
N = numerator of fraction which fixes the number of slots per pole per phase
p = number of pole pairs
P = smallest integer which makes d an integer
$q = N/\beta$ number of slots per pole per phase
y = winding pitch (back pitch + front pitch)
β = denominator of the fraction which fixes the number of slots per pole per phase

Operation of Large D-C Motors From Controlled Rectifiers

A. SCHMIDT, JR.

W. P. SMITH
Membership Application Pending

Synopsis: The d-c output voltage of a typical power rectifier has more ripple than the output of a d-c generator. The ripple increases as the number of rectifier phases is decreased. It also increases as the rectifier voltage is reduced by phase retard. The voltage ripple affects the performance of d-c motors in the following respects:

1. Heating.
2. Commutation.
3. Speed regulation, particularly when current is discontinuous.

D-c motors constitute the major part of the load of general purpose power rectifiers. It is a matter of experience that d-c motors in the fractional horsepower and small integral horsepower ranges must be derated when they are operated over a wide speed range from rectifiers with voltage control. The factors which result in derating of these motors are present to a very limited extent in general purpose rectifiers, which usually have six or more phases and are seldom operated with more than 15 per cent phase control. Hence little consideration has been given to the derating of motors connected to such rectifiers. In recent times the extension of controlled rectifier drives to d-c motors in the range of 100 horsepower or more has raised the question of modifying the rating of these larger motors when operated from rectifiers with phase control. It is the purpose of this paper to discuss the factors present in controlled rectifiers which affect the rating of connected motors and to describe the results of tests made on a 400-horsepower motor driven by both a 6-phase and a 3-phase controlled ignitron rectifier. Emphasis in this paper will be placed on the practical significance of the test results obtained.

Effects of Rectifier Supply on Motor

Voltage and Current Ripple

Case (1) Continuous Current. Conventional methods of rectifier circuit analysis assume an infinite d-c reactance. This assumption results in steady d-c current and facilitates circuit analysis. Since we are concerned here with the effect of a current which is not steady, but pulsates at some multiple of the supply frequency, we must consider the value of circuit inductance since this is a factor in determining the ripple.

In the case of continuous (that is, nonintermittent) current, the d-c inductance is made up of two parts, (1) the inductance of the load, and (2) the average inductance of the conducting windings of the rectifier transformer.

With usual ratios of resistance to inductance, resistance has a negligible effect on ripple.

Figure 1 shows the voltage and current of a typical 6-phase rectifier having a counter electromotive force load with finite inductance. The voltage is made up of a d-c component and an a-c component whose frequency depends on the number of phases in the rectifier and the supply frequency. The average value, rms value, and harmonic content of the a-c component may be determined by established methods.[1]

At a moment when the voltage of the rectifier is at its average value and rising, the motor current will be at its minimum value. If this time be designated by t_0 and the next instant of equal rectifier voltage by t_1, the motor current will vary over the interval by an amount

$$\Delta I = \frac{\int_{t_0}^{t_1}(E_d - e_d)dt}{L_d}$$

$\int_{t_0}^{t_1}(E_d - e_d)dt$ is proportional to the average value of the rectifier ripple voltage. Thus, the current ripple is a function of average voltage ripple of the rectifier and the d-c inductance. The average ripple voltage of the rectifier depends on the number of phases, the angle of phase retard, the rectifier load, and the transformer reactance. Figure 2 shows the average ripple voltage of rectifiers as a function of phase retard angle and number of phases for a typical value of transformer reactance. The total current variation with q phases is

$$\Delta I = \frac{E_{av}}{2qfL_d}$$

Thus, the current ripple can be determined if the number of rectifier phases, the amount of phase retard, and the total d-c circuit inductance are known.

Case (2) Discontinuous Current. Conditions are sometimes present where the half-amplitude of the ripple current exceeds the average value of current in the motor, in which case the current will not be continuous. Figure 3 illustrates the voltage and current relations in such a case. If conduction is discontinuous, a given anode cannot start to conduct until its voltage exceeds the counter electromotive force of the motor plus the arc drop voltage. Conduction may be delayed to a later time by phase control of the rectifier. In Figure 3 conduction is assumed to start at some time after the anode voltage zero represented by the angle ψ. During the period when the anode voltage exceeds the motor voltage, current will increase to some maximum value which is reached when the anode voltage falls back to the value of the motor voltage. At this point, the stored energy in the inductance will maintain current for some period. If resistance is neglected, the current will reach zero at such a time that the integrated volt-seconds difference between the anode voltage and counter electromotive force is the same for both sections of the conducting period. In other words, areas A and B of Figure 3 are equal.

Paper 48-164, recommended by the AIEE electronic power converter committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Figure 1 (left). Direct voltage and current of 6-phase rectifier with moderate value of load inductance

Figure 3. Voltage and current relations in controlled rectifier with noninductive counter electromotive force load

Regulation

Figure 4 shows the regulation curve of rectifiers with various amounts of phase retard and carrying discontinuous current. The derivation of these curves is shown in the Appendix. Zero resistance is assumed. The arc drop of the rectifier is treated as part of the total counter electromotive force.

It will be noted that if the conducting period of one anode exceeds $360°/q$ then conduction of current to the load is continuous and not discontinuous. In such a case the regulation of the rectifier approximates the figure derived when rectifier circuit theory is applied to the case with infinite d-c inductance. When conduction is discontinuous, it is immaterial whether the inductance is confined to the d-c circuit or the a-c circuit or is distributed between the circuits. Figure 4 indicates the end of discontinuity for rectifiers having different numbers of phases.

Temperature Rise

A motor operating on rectified power may be expected to show a greater than normal temperature rise because of the greater losses resulting from the effects of ripple current. These added losses are divided between the current carrying and flux carrying parts of the machine. The former are increased by the extra eddy current losses, by the increase in effective resistance caused by skin effect, and by reason of the fact that the ratio of rms to average current is greater than unity. The flux carrying material in the motor will show increased eddy current and hysteresis loss when ripple current is present because of resulting flux pulsations. Such losses will be accentuated in motors having series fields. The magnitude of all these extra losses is a function of the magnitude and frequency of the ripple current and thus is influenced by the degree of phase retard, increasing as the angle of retard is increased.

Commutation

The commutating performance of a d-c motor operating from a rectifier power supply is adversely affected when the frequency of the ripple current is so high that the commutating pole flux is no longer proportional to and in phase with armature current. When this occurs the armature reaction is not properly compensated for and sparking may result. Nonproportionality may be caused by reduction of commutating pole flux by eddy currents, phase displacement due to iron loss, or by saturation of the pole at current maxima.

Motor Tests With Rectifier Supply

In order to evaluate the effect of a polyphase rectifier supply on a medium or large sized motor, tests were made on a 400-horsepower, 375/750 rpm, 230-volts, direct current, stabilized shunt wound, force ventilated motor of a type commonly used for steel mill and electric shovel applications. Tests were made using both a

See Appendix I for explanation of symbols

6-phase and 3-phase power supply. To permit direct comparisons with normal performance, duplicate tests were made concurrently using a d-c generator as a source of direct current. The test work performed was intended to indicate what effect the rectifier supply would have on the temperature rise, commutation, and speed regulation of a large motor, and in addition a number of oscillograms of current, voltage, and so forth were made in order to evaluate the magnitude of the ripple currents present. The motor was equipped with two exploring coils, one on the tip of one of the main poles and one on the tip of one of the commutating poles. The purpose of these coils was to determine the magnitude of the pulsating component of flux in the poles, and to determine the phase relationship between commutating pole flux and armature current.

Temperature Rise

The extent to which the added losses alter the observed temperature rise was determined by making comparative heat runs using a conventional d-c source, a 6-phase rectifier and a 3-phase rectifier. Comparisons were made on the basis of the same average current since this results in the same torque. In every instance the motor was run under constant load, with normal forced ventilation, until the temperature ceased to rise; whereupon the machine was shut down and the temperature rise of all parts measured by means of thermocouples and mercury thermometers. In addition the average temperature rise of the armature winding was obtained by measuring the hot resistance at the completion of each heat run, and comparing this with the resistance at a known temperature.

The results of the heat runs are tabulated in Table I. Temperature rises are given in per-unit, the values obtained with conventional d-c power being expressed as unity.

Table I. Comparison of Motor Temperature Rises With Generator and Rectifier Supplies

Location of Rise	Temperature Rise. Per Unit Base is Rise With Generator Supply					
	Full Voltage			25 Per Cent Voltage		
	Generator Supply	Rectifier Supply 6-Phase	Rectifier Supply 3-Phase	Generator Supply	Rectifier Supply 6-Phase	Rectifier Supply 3-Phase
Average of rises measured on armature	1.000	0.939*	1.071	1.000	1.061	1.367
Average of rises measured on frame and field structure	1.000	0.986*	1.200	1.000	1.157	1.666
Average of rises measured on field coils	1.000	1.015	1.147	1.000	1.079	1.523
Average of rises measured on pole tips	1.000	0.973*	1.188	1.000	1.306	2.080
Armature rise by resistance measurement	1.000	1.037	0.824*	1.000	1.207	2.243*

*Inaccuracies of measurement believed excessive in terms of per unit base.

Commutation

Commutating performance was evaluated by means of "black band" tests, which are familiar to most d-c machine designers. In this type of test the strength of the commutating field is varied above and below normal by means of a booster generator connected across the commutating field winding and the maximum and minimum field strengths at which sparkless commutation exists are determined. Such readings are usually taken at a number of loads and plotted on a chart with load amperes as the abscissae and amperes added to or subtracted from the commutating pole winding as positive and negative ordinates respectively. When the points of maximum commutating field current for sparkless commutation are connected by one line and the points of minimum commutating field current for sparkless commutation by another line, the area between represents a region of sparkless or "black" commutation and hence is commonly known as the "black band."

It will be appreciated at once that the width of this band is an indication of the ability of the machine to operate satisfactorily when commutating pole flux and

Figure 5. Black band commutation curves for 230-volt 400-hp 375/750 rpm motor operating with generator supply

Figure 6. Black band commutation curves for 230-volt 400-horsepower 375/750 rpm motor operating with 6-phase controlled rectifier supply

Figure 7. Black band commutation curves for 230-volt 400-horsepower 375/750 rpm motor operating with 3-phase controlled rectifier supply

Figure 8. Observed regulation of 3-phase rectifier with 400-horsepower 230-volt motor

armature current are not matched as to magnitude and phase relationship.

In this investigation tests were made under three general conditions of operation as follows:

1. Reduced voltage, full field excitation.
2. Full voltage, full field excitation.
3. Full voltage, reduced field excitation.

Each of these conditions was investigated with conventional d-c supply, 6-phase rectifier supply and 3-phase rectifier supply, with the results shown in Figures 5, 6, and 7. The ripple component of current was prevented from flowing around the commutating field and through the booster generator by inserting a reactor in one of the booster generator leads.

Measurements were made of exploring coil voltages under various conditions of operation.

Speed Regulation

The speed regulation of any d-c motor is a combination of two factors; the inherent regulation of the motor and the regulation of its power supply. In the case of a rectifier power supply regulation is only a few per cent over the load range except when the load current becomes discontinuous. As pointed out earlier in this paper the voltage regulation of the rectifier is relatively large when discontinuous currents exist and this is reflected in the speed regulation of the motor. Since discontinuous currents occur mainly at relatively light loads and large values of phase retard, it is under low torque and speed conditions that motor speed regulation is increased. This will not be a disadvantage in many cases where lowered voltages occur only during accelerating periods, but in other applications where creeping speeds at low torque are required this increased speed regulation may require consideration.

In order to obtain factual data regarding this effect voltage regulation curves were made with various values of phase retard. The results have been plotted and compared to calculated performance in Figures 8 and 9.

Ripple Current

In order to evaluate the magnitude and wave shape of the d-c currents and voltages, oscillograms were taken showing load voltage, armature voltage, armature current, and anode current for one tube under various conditions of load and phase retard. Representative results are shown in Figures 10 and 11.

Calculated values of ripple current were derived from the angle of phase retard of the rectifier and the measured motor inductance. Typical values are given in Table II.

Discussion of Test Results

Temperature Rise

The heat run results shown in Table I show that in the motor under test, the field structure temperature rise is increased by a larger percentage than is the rise of the armature. However, the normal temperature rise of the field is generally less than that of the armature so that in most cases the armature is still the hottest part. This particular motor, as noted before, was run with forced ventilation, probably resulting in less increase in rise at reduced voltage than would have been experienced with a self-ventilated motor. Examination of the data given in Table I shows that at full voltage the 6-phase rectifier power supply does not appreciably affect the temperature rise but the 3-phase rectified power supply resulted in a 10 to 20 per cent increase in temperature rise. At 25 per cent voltage where much greater ripple currents exist the temperature rise was from 10 to 20 per cent greater than normal with a 6-phase rectifier but was from 35 to 120 per cent greater with a 3-phase rectifier.

Commutation

Comparison of the black bands shown in Figures 5 and 6 will show clearly that the 6-phase rectifier has practically no

Table II

Number of Phases	Degree Phase Retard	Load Ampere	ΔI, Calculated	ΔI, Observed
3	0	1,500	435	480
3	27	1,500	640	700
3	63	1,500	1,050	1,120
6	66	1,600	230	220
6	26	1,500	120	130

Figure 9. Observed regulation of 6-phase double wye rectifier with 400-horsepower 230-volt motor

adverse effect on the commutating characteristics of this motor even at reduced voltages. Some narrowing of the band at reduced voltage is discernible but since the band is so wide sparkless commutation is obtained over a wide range of load. This widening of the band at reduced voltages is inherent in all d-c motors and is a most fortunate circumstance since it means that any motor is thus better able to handle the increased ripple currents which exist when the rectifier voltage is lowered by retarding the firing.

A comparison between performance with a generator supply and with a 3-phase rectifier as indicated by reference to Figures 5 and 7, shows a definite inferiority of performance with 3-phase rectified power, although in this case the observed commutation was still sparkless over most of the load range.

In an effort to determine the extreme limits of commutating ability the motor was supplied with 3-phase rectified power at 200 volts from a 600-volt phase-retarded rectifier. With the ripple current thus intensified at approximately normal voltage the commutation was very poor, particularly at increased speeds obtained by field weakening. However, such conditions are considered abnormal and would not occur in practice.

Measurements of voltage on the commutating pole exploring coils indicated that the ripple in the commutating flux was less percentagewise than the ripple in the armature current by an amount approximating the narrowing of the black band width. This confirms the presence of eddy currents in the poles and indicates their order of magnitude.

In general it is thought that reducing the voltage of a 6-phase rectifier by phase control will not result in poor commutation, assuming that the rectifier when fully advanced does not deliver more than normal motor voltage. This is true because the margin for good commutation varies inversely with speed and this in-

Figure 10. Current and voltage relations in 400-horsepower 230-volt motor driven by 300-volt 3-phase rectifier at 215-volts 150-amperes

creased margin at low speeds more than compensates for the detrimental effects of the increased ripple component in the current.

Regulation

The observed voltage regulation of the rectifier shown in Figures 8 and 9 agree with performance calculated from the inductance of the motor and the rectifier.

It will be noted that the subject motor is a medium speed machine. A higher speed motor, or one having compensating poles, may have considerably less inductance. This will result in discontinuity of current at higher values of load, requiring a greater range of rectifier phase control if it is desired to maintain constant motor speed over a considerable load range.

Conclusions

Motor Inductance

It should be borne in mind that the unique result of application of a rectifier as a power source to a motor is ripple current and that the magnitude of this ripple current varies inversely with the motor inductance. The results of tests on a particular machine must be interpreted with this in mind.

Temperature Rise

It appears that no derating due to increased temperature rise is indicated for operation on 6-phase rectifiers at full voltage. Some slight derating might be required if extended operation at low voltage were contemplated, but it is probable that most duty cycles would not include enough low voltage operation to necessitate derating the machine.

When operating from a 3-phase rectifier delivering full voltage, a certain amount of derating would be necessary in order to maintain rated temperature rise. When operating at 25 per cent voltage on the 3-phase rectifier considerable derating would be necessary to prevent overheating of the motor. However, the use of 3-phase variable voltage rectifiers with motors larger than 75 horsepower is not generally contemplated.

The fact that the greatest increase in temperature rise in every case was in the frame and field structure of the machine would seem to indicate that considerably increased iron loss is present and it may be necessary in some cases to design the stationary magnetic flux carrying structure for lower losses. Since heat in the field structure influences the field coil temperature, the design of field coils may require review.

Commutation

No discernible lessening of commutating ability of the subject machine appears to result when a 6-phase rectifier is used. Even at reduced voltage the machine performs practically as well as with a generator supply. With a 3-phase rectifier, the width of the "black bands" was reduced, and machines having very narrow black bands on a conventional d-c supply may show distress when operated with 3-phase rectified power.

Regulation

Reduced voltage operation of the rectifier will result in poor speed regulation of connected motors at light loads, particularly in the case of low-inductance machines, unless a suitable voltage regulator is applied to the rectifier.

Appendix I. List of Symbols

e_d = instantaneous d-c volts
E_d = average d-c volts or motor counter electromotive force
E_{av} = average value of ripple volts
E_M = peak value of rectifier d-c volts with no phase retard
I_d = average value of rectified current
L_d = d-c circuit inductance
q = number of rectifier phases
X = total series reactance of rectifier circuit

Appendix II

Figure 3 shows the voltage and current relations for a rectifier consisting of a single rectifying element supplied by an a-c voltage having a crest value E_M, with a constant potential load E_d and a circuit inductance L. Current flow cannot start before the anode voltage reaches the value E_d. It may be delayed by grid control to a later time.

Let ψ be the angle at which conduction starts. Current will increase till the time γ, where the anode voltage is equal to E_d. Current will then decrease and reach zero at time θ, when the inductance will have returned to the circuit the energy stored in it during the interval from ψ to γ. If no circuit losses exist, areas A and B are equal.

Figure 11. Current and voltage relations in 400-horsepower 230-volt motor driven by 300-volt 6-phase (double wye) rectifier at 93-volts 1,500-amperes

$$A = E_M \int_\psi^\gamma \sin \omega t \, dt - E_d(\gamma - \psi)$$

$$= B = E_d(\theta - \gamma) - E_M \int_\gamma^\theta \sin \omega t \, dt$$

whence

$$\frac{E_M}{\omega}(\cos \psi - \cos \theta) = E_d(\theta - \psi)$$

Since

$$E_d = E_M \sin \gamma$$

$$\sin \gamma = \frac{\cos \psi - \cos \theta}{\omega(\theta - \psi)}$$

The current i_d is derived from the equation

$$L\frac{di_d}{dt} + E_d = E_M \sin \omega t$$

The solution of this equation is

$$i_d = \frac{E_M}{\omega L}(\cos \psi - \cos \omega t) - \frac{E_M}{L} \sin \gamma(t - \psi)$$

The average current is

$$I_d = \frac{1}{2\pi}\int_\psi^\theta i_d \, dt$$

$$= \frac{E_M}{2\pi X}[\sin \psi - \sin \theta + {}^1/_2(\theta - \psi)(\cos \psi + \cos \theta)]$$

$$= \frac{E_M}{2\pi X}F(\psi, \theta)$$

where

$$F(\psi, \theta) = \sin \psi - \sin \theta + {}^1/_2(\theta - \psi)(\cos \psi + \cos \theta)$$

If the rectifier has q anodes, the total output is

$$I_d = \frac{qE_M}{2\pi X}F(\psi, \theta)$$

provided that the reactive voltages accompanying conduction in one anode do not affect conduction by any other anode. This condition is satisfied if all the inductance is in the anode leads. It is also satisfied if the conducting period of an anode is less than $2\pi/q$.

Doubly Chorded or Doubly Shifted Fractional-Slot Lap and Wave Windings

M. M. LIWSCHITZ
MEMBER AIEE

THE PATTERN used most frequently for laying out balanced fractional-slot windings is that for maximum distribution factor of the main wave. From this pattern, a large number of other balanced patterns can be obtained by a cyclic shifting of coils from one phase to the other inside the same repeatable group. The distribution factor of the main wave of these latter patterns is always smaller than that of the former pattern. The distribution factors of the harmonics are partially smaller, partially larger than those of the former pattern, so that the values of the harmonic (differential) leakage of the different patterns do not differ much from each other. The advantage of the pattern with a cyclic shift of coils inside the same repeatable group is that it makes it possible to reduce the distribution factors of one or several undesirable electromotive force or magnetomotive force harmonics. The aim of this paper is to show that the same effect of reduction of certain harmonics can be achieved by shifting of repeatable groups with respect to each other. This method of reduction of harmonics has the advantage that it is applicable to lap as well as to wave windings, while the cyclic shift of coils is limited to lap windings. Further, the shift between the repeatable groups necessary to achieve desirable results is seen immediately, while with the cyclic shift of coils inside the same repeatable group, the trial and error method must be applied. On the other hand, the shifting of repeatable groups reduces the maximum possible number of parallel circuits.

The normal chording of a winding is nothing more than a shift of the lower layer with respect to the upper layer. When repeatable groups are shifted with respect to each other, the fractional-slot winding becomes doubly shifted or doubly chorded and two pitch factors are to be considered. In many practical cases, it becomes necessary to reduce several harmonics simultaneously. In these cases, the double chording and cyclic shift of coils can be combined.

Cyclic Shift of Coils Inside the Same Repeatable Group of a Lap Winding

Figure 1 shows the slot star[1] of a 3-phase 20-pole lap winding with $q=N/\beta=17/5$ (for symbols see List of Symbols). There are 17 slots per phase in five-poles. For maximum distribution factor with respect to the main wave, the first 17 slots (1, 42, 32 . . . . 14, 4, 45) are assigned to phase A; the following 17 slots (35, 25, 15 . . . . 48, 38, 28) to phase C; and the last 17 slots to phase B. The slots assigned to phase A are indicated by crosses; those assigned to phase C by rectangles; and those assigned to phase B by circles.

Figure 2 shows the slot star for the same winding with slots 4, 38, and 21 subjected to a cyclic shift. Slot 4, which in Figure 1 belongs to phase A, is shifted to phase C; slot 38, which in Figure 1 belongs to phase C, is shifted to phase B; and slot 21, which in Figure 1 belongs to phase B, is shifted to phase A.

The distribution factors of the main wave and of a part of the harmonics are as shown in Table I.

$n'=p=10$ is the main wave. The distribution factor of this wave is reduced slightly by the cyclic shift, while for example, the distribution factor of the wave of the order $n'=14$, which is the 1.4th harmonic with respect to the main wave is reduced by 77.4 per cent. If there is a danger that an 8-pole force wave, produced by the main wave and the wave of the order $n'=14$, may produce a 120-cycle vibration and noise, the cyclic shift of coils inside the same repeatable group proves very useful. The main wave produces an 8-pole force wave also with the harmonic of the order $n'=6$, the distribution factor of which is slightly increased by the cyclic shift of coils. However, the pitch factor of the latter harmonic is smaller than that of the wave $n'=14$, and it is also more damped by the rotor than the wave of the order $n'=14$.

Shift of Repeatable Groups with Respect to Each Other

The shift of repeatable groups with respect to each other does not affect the distribution factors, but introduces a second pitch factor. The first pitch factor is due to the fractional coil pitch.

The angle between two adjacent vectors of the slot star is

$$\alpha_m=\frac{180^\circ}{mN} \tag{1}$$

If the lower layer is shifted with respect to the upper by k_1 angles α_m, the first pitch factor, due to fractional coil pitch is

$$K_{1pn}'=\text{Cos } k_1(\alpha_n'/2) \tag{2}$$

and, if the repeatable groups are shifted with respect to each other by k_2 angles α_m the second pitch factor is

$$K_{2pn}'=\text{Cos } k_2(\alpha_n'/2) \tag{3}$$

The total pitch factor of the winding is

$$K_{1pn}'\times K_{2pn}'$$

If in the equation

$$d=\frac{mNP+1}{\beta} \tag{4}$$

Paper 48-163, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Manuscript submitted November 12, 1947; made available for printing February 27, 1948.

M. M. LIWSCHITZ is a professor with the Polytechnic Institute of Brooklyn, Brooklyn, N. Y., and also is connected with the Westinghouse Electric Corporation, East Pittsburgh, Pa., as consulting engineer.

Table I

$n'=$	2	6	10	14	22	26	30	50	70	110	130	170	
$K_{dn'}=$	0.031	0.104	0.955	0.053	0.031	0.045	0.638	0.191	0.138	0.090	0.076	0.156	without cyclic shift
$K_{dn'}=$	0.081	0.116	0.951	0.012	0.084	0.031	0.616	0.173	0.113	0.051	0.030	0.235	with cyclic shift

P is the smallest integer which makes d an integer, then,

$$\alpha_n' = n'd\alpha_m \frac{\beta}{p} \text{ when } P \text{ is even}$$

$$\alpha_n' = n'd\alpha_m \frac{\beta}{p} + 180° \text{ when } P \text{ is odd and } \beta \text{ is even}$$

$$\alpha_n' = n'(d\alpha_m + 180)\frac{\beta}{p} \text{ when } P \text{ is odd and } \beta \text{ is odd} \quad (5)$$

The harmonics which occur in 3-phase windings with no zero sequence currents are

$$n' = \frac{p}{\beta}\gamma \quad \gamma = 1, 5, 7, 11, 13 \ldots \quad (6)$$

when β is odd, and,

$$n' = \frac{2p}{\beta}\gamma \quad \gamma = 1, 2, 4, 5, 7, 8 \ldots \quad (7)$$

when β is even.

Considering the wave of the order $n'=14$ of the previously treated lap winding (Figure 1), a value of k_2 is to be determined which makes this harmonic as small as possible. For this winding

$$d = \frac{3\times 17\times P+1}{5} = 41 \text{ with } P=4$$

$$\alpha_n' = n'\times 41\times\frac{180}{3\times 17}\times\frac{5}{10} = n'\times 72.35°$$

Hence, for the wave of the order $n'=14$

$$\alpha_{(n'=14)} = 14\times 72.35° = 293° \text{ and}$$
$$\alpha_n'/2 = 146.5°$$

With $k_2=3$, the second pitch factor becomes

$$K_{p(n'=14)} = \cos 79.5° = 0.182$$

Comparing the wave $n'=14$ of the cyclic shift of coils with that of the shift of repeatable groups, the result is

$$K_{d(n'=14)} = 0.012 \text{ with cyclic shift of coils}$$

$$K_{d(n'=14)}\times K_{p(n'=14)} = 0.053\times 0.182 = 0.0096 \text{ with shift of repeatable groups}$$

Applying both shifts,

$$K_{d(n'=14)}\times K_{p(n'=14)} = 0.012\times 0.182 = 0.0022$$

and the wave $n'=14$ becomes very small.

The first pitch factor is independent of both kinds of shift. If the coil width is equal to eight slot pitches, the value of k_1 is equal to 11.

The slots which are to be assigned to the three phases for the shift $k_2=3$ can be found from the slot star or simpler from the d-series which the vectors of the slot star follow. This series or the slot star, Figure 1, yields for the first repeatable group of phase A, the slots

1	42	32	22	12	2	43	33	23	13
				3	44	34	24	14	4	45

When there is no shift between the repeatable groups, the second repeatable group of phase A consists of the slots

52	93	83	73	63	53	94	84	74	64
			54	95	85	75	65	55	96

In order to produce a shift of $k_2=3$ angles α_m between the first and second repeatable groups, the slots of the second repeatable group assigned to phase A must be

73	63	53	94	84	74	64	54	95	85
			75	65	55	96	86	76	66

that is, the first three slots of phase C are to be assigned to phase A, the first three slots of phase B are to be assigned to phase C, and the first three slots of phase A to phase B. The same applies to the fourth repeatable group with respect to the third.

Due to the shift of repeatable groups, the maximum possible number of parallel circuits of the winding considered is reduced from four to two. In general, there will be maximum possible p/β parallel circuits instead of $2\,p/\beta$.

Since the influence of the shift of repeatable groups appears in the form of a pitch factor, all harmonics are reduced by this shift. However, in the case when β equals an odd number, the shift of repeatable groups introduces even harmonics.

The method of shifting repeatable groups will be demonstrated also on a wave winding. It is shown in a companion paper[3] that a balanced wave winding can be made for the same fractional number of slots per pole per phase for which a balanced lap winding is possible. The investigation of the wave windings, as well as that of the lap windings, is here based upon the slot star or, what is the same, upon the d-series.

A 3-phase 10-pole wave winding with $q=11/5$ will be considered. For this winding, $N=11$, $\beta=5$, $d=20$, $y=13$, and $a=-1$. The winding goes opposite to the numbering of the slots. With two conductors per slot and left-hand coils, the lower conductors shown in Table II are assigned to the three phases when there is no shift of repeatable groups.

Each phase consists of two waves with the same number of coils. When the two repeatable groups are shifted with respect to each other by $k_2=3$ angles α_m, the conductors assigned to the three phases are as shown in Table III.

Each phase consists of two waves with unequal numbers of coils which must be connected in series.

List of Symbols

a = number of angles α_m between the vectors x and $x+y$ of the slot star

d = difference between two slots which correspond to two adjacent vectors of the slot star

k_1 = number of angles α_m by which the lower layer is shifted with respect to upper layer

k_2 = number of angles α_m by which two repeatable groups are shifted with respect to each other

K_{1pn}' = pitch factor of the n'-th harmonic due to fractional coil pitch (first pitch factor)

K_{2pn}' = pitch factor of the n'-th harmonic due to shift of repeatable groups (second pitch factor)

m = number of phases

n' = order of the harmonic with respect to a fundamental whose wave length is equal to the circumference of the armature

N = numerator of the fraction which fixes the number of slots per pole per phase

$q \times \beta$ = number of slots per phase per repeatable group

p = number of pole pairs

P = number of full pole pitches between two slots which correspond to two adjacent vectors of the slot star

$q = N/\beta$ = number of slots per pole per phase

y = winding pitch

$\alpha_m = 180/mN$ = angle between coils with respect to main wave

α_n' = angle between coils with respect to the n'-th harmonic

β = denominator of the fraction which fixes the number of slots per pole per phase

Steady-State Stability of Synchronous Machines as Affected by Angle-Regulator Characteristics

C. CONCORDIA
FELLOW AIEE

THERE has recently been some discussion of the benefits (with respect to electric power system stability) to be obtained by the use of a properly designed angle regulator.[1-5] An angle regulator applied to a synchronous machine is defined here as a regulator that varies the machine excitation voltage in response to changes in the angle between the rotor interpole axis and the effective system voltage so as to tend to restore the initially set angle. The purpose of this paper is to present the results of an analytical exploration of the possibilities of the angle regulator as regards stability. In particular, since voltage regulators are already extensively used, and since their use as aids in power-system stability has already been studied,[6,7,8] it has seemed appropriate to compare the action of an angle regulator with that of a voltage regulator.

Conclusion

The principal conclusion of the present analysis is that the dynamic actions of the angle and voltage regulators near the system stability limit are essentially equivalent, so that their effects on stability can by proper regulator design be made practically indistinguishable. The need for an angle regulator cannot therefore be demonstrated on the basis of stability requirements.

General Discussion

In the normal operation of a synchronous generator over its load range it is customary, and indeed it seems highly desirable and almost necessary, to maintain voltage, rather than load angle constant. Thus if an angle regulator were used it would have to be biased by a voltage regulator at least in the steady state. If it appears worth while to have temporarily, a somewhat higher excitation than would result from the normal action of a voltage regulator (as was true in some of the disturbances studied in connection with reference 8), it seems at least as simple to accomplish this by temporarily modifying the action of the voltage regulator as by introducing the concept of holding angle.

The conclusion that voltage and angle regulators are dynamically practically indistinguishable is based upon an analysis some of the results of which will be presented and discussed later. However, it may be worth while to advance first an argument based on physical considerations. A simple case of an unregulated synchronous machine connected through a tie line to an infinite bus, or two machines connected together and transferring power, may be easily visualized. It is evident that as the machines swing against each other the variation of terminal voltage and machine rotor angle occur very nearly in phase, the angle increasing as the voltage decreases. Armature and amortisseur transients are sufficiently fast to be neglected, so that the only shift in phase is produced by the field resistance or finite field time constant. For an abrupt increase in angle, the terminal voltage will first decrease as determined by the machine transient reactances, and then decrease still more to the value determined by the synchronous reactances. For the usual frequencies of oscillation (greater than a tenth of a cycle per second), the phase shift is very slight and the magnitude of the voltage variation may be computed approximately from the transient reactances. However, this slight phase shift is found to be beneficial, as the present analysis has shown that somewhat less damping torque (as produced by local load or the machine amortisseur, or by introducing response to the rate of change of voltage or angle) is required for the voltage regulator than for the angle regulator. Another difference in performance over the load range is that as the operating angle increases the voltage drop for a given angle increase increases, so that the voltage regulator tends to act more and more in response to power-input or system changes as the stability limit is approached. This effect is illustrated for a simple case in Figure 1.

Results of Analysis

Figure 2 shows some of the results of calculations of the stability limits as affected by an angle regulator of the simple form

$$\Delta E = \frac{a_2}{T_r p + 1} \Delta \delta \qquad (1)$$

where

E = generator field voltage
δ = generator angle relative to infinite bus
a_2 = regulator amplification factor
T_r = regulator (or exciter) time constant

The system considered is the same as that for which the effects of a voltage regulator of similar form were shown in Figures 1 and 2 of reference 7, and consists of a synchronous machine of unit synchronous reactance connected to an infinite bus through a tie line of unit reactance, with the machine terminal voltage and power

Paper 48-165, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Manuscript submitted February 11, 1948; made available for printing April 2, 1948.

C. CONCORDIA is with the central station engineering division of the General Electric Company, Schenectady, N. Y.

All the stability calculations for the angle-regulator system discussed in this paper were made by Miss M. V. Barry.

Figure 1. Effect of load angle δ on change of terminal voltage e_t with angle—synchronous machine and tie line

$X_{machine} = X_{line}$
$E_{machine} = e_{line}$
$e_{to} = PF_{terminal} = 1.0$

factor maintained at unity in the steady state. Figure 1 of reference 7 is repeated here as Figure 3 for ready comparison.

Figures 2 and 3 show that the maximum gains in power limit (for all these cases the power P is simply $P = \tan \delta/2$ so that for example an angle δ of 110 degrees corresponds to a power of 1.43 per unit) are identical for either regulator. The shapes of the curves are also practically the same, the range of permissible amplification (expressed as the ratio of maximum to minimum amplification) being only very slightly less for the angle regulator than for the voltage regulator. For example, on curve C at $\delta = 100$ degrees the permissible range of a_1 (the voltage regulator amplification factor) is from -0.54 to -19 (a range of 35 to 1), while the corresponding range of a_2 (the angle regulator amplification factor) is from $+0.27$ to $+7.6$ (a range of 28 to 1).

The actual magnitude of the power gain depends in any case on the system conditions, in particular on the relative importance of the machine reactance and the tie-line reactance. In the interpretation of Figures 2 and 3 it is convenient to note[7] that the maximum power limit for curve A of both figures is simply that which would be calculated by using machine transient reactance instead of synchronous reactance (using constant field flux linkages instead of constant field current). In long-distance power transmission the machine reactance may be relatively smaller so the percentage gains in power limit would be correspondingly smaller, but would still be appreciable and worthy of consideration.[8]

The concept of using transient reactance provides a quick means for estimating the gain which may be obtained by use of a proper regulator, as both calculations and tests have shown that the effects may be approximated by using a reduced machine reactance which may approach the transient value.

Figure 4 shows the effect of adding a slip-torque damping term $T_d p\delta$ to the torque equation of the synchronous machine, as may arise from the amortisseur, prime mover torque-speed characteristic, or local load. There is no effect on the maximum increase in power obtainable by the angle regulator, but the stable region is considerably extended at light load. In the case of a voltage regulator, the stability limit appears more or less like curve B of Figure 4 even for no slip-torque (in part because of the voltage-angle characteristic of Figure 1), while the addition of slip-torque produces an additional stable region at very high regulator amplification factors which may reach greater power limits, as illustrated in Figures 10 and 11 of reference 8 and in Figure 5 of this paper.

The effect of introducing a signal into the angle regulator proportional to slip, or rate of change of angle, $p\delta$ was studied by modifying the regulator Equation 1 to the form:

$$\Delta E = \frac{1}{T_r p + 1}(a_2 p\delta + a_2 \Delta\delta)$$
$$= \frac{kp+1}{T_r p + 1} a_2 \Delta\delta \qquad (2)$$

where

$$k = a_3/a_2 \qquad (3)$$

It is evident that by making $k = T_r$, all cases are made equivalent to the case $T_r = 0$ or no time lag in the exciter. This permits the maximum operating angle to approach 115.5 degrees as shown in Figure 2, curve A but also reduces considerably the permissible range of amplification factor. Moreover calculations have shown that as long as the exciter time constant T_r is appreciably greater than zero, making $k = T_r$ produces the maximum gain. As k varies between zero and T_r the maximum gain increases slightly and the permissible range of amplification factor a_2

$x_d' = 0.3$

Figure 5. Steady-state stability limit with voltage regulator—effect of damping torque coefficient T_d—synchronous machine and tie line

$T_r = 400$ radians $\quad x_d = x_q = x = 1.0$
$T_o = 2{,}000 \quad e_{to} = PF_{to} = 1.0$
$M = 4{,}000 \quad r = 0$
$x_d' = 0.3$

decreases. When k is made greater than T_r the maximum gain decreases again and the permissible range also decreases. If the exciter time lag T_r is extremely small or zero, considerable gains can be made by introducing the response to slip, but this would be difficult to realize practically. Thus in the practical range the effect of response to slip appears to be unimportant.

Figure 6 shows the effect of the angle regulator operating in combination with a voltage regulator. Both regulators have the same time lag, as this lag has been assumed to occur principally in the exciter rather than in the regulator proper.

The regulator equation is of the form

$$\Delta E = \frac{1}{T_r p + 1}(a_1 \Delta|e_t| + a_2 \Delta\delta)$$

where a_1 is the voltage regulator amplification factor, and $|e_t|$ is the absolute magnitude of the generator terminal voltage. Figure 6 shows that the only effect of adding the voltage regulator is to change the required angle-regulator amplification factor, the maximum gain being unaffected and occurring when

$a_2 \cong {}^1/_2 a_1$

Analysis

The power system considered consists of a synchronous machine connected through a tie line to an infinite bus. The regions of stable operation in the steady state have been determined by examining the equations for small displacements of this machine from its equilibrium point for various loadings, always starting from unit voltage and power factor at the terminals of the machine.

Referring to reference 7, equations 1–15 and 30–32, and using the same notation and assumptions one may write the following equations for changes of voltage:

For the machine:

$$\Delta e_d = x_q \Delta i_q \tag{4}$$

$$\Delta e_q = G(p)\,\Delta E - x_d(p)\,\Delta i_d \tag{5}$$

where

$$G(p) = \frac{1}{T_o p + 1} \tag{6}$$

$$x_d(p) = \frac{x_d' T_o p + x_d}{T_o p + 1} \tag{7}$$

e_d, e_q = direct- and quadrature-axis components of machine terminal voltage
i_d, i_q = direct- and quadrature-axis components of armature current
T_o = machine open-circuit field time constant
x_d, x_d' = machine synchronous and transient reactances respectively

Equations 6 and 7 are for a machine with no amortisseur. For the tie line:

$$\Delta e_d = -x\,\Delta i_q + e \cos\delta\,\Delta\delta \tag{8}$$

a_1 = amplification factor of voltage regulator

$T_r = 400$ radians
$T_o = 2{,}000$
$M = 4{,}000$
$x_d = x_q = x = 1.0$
$e_{to} = PF_{to} = 1.0$
$r = 0$
$x_d' = 0.3$

$$\Delta e_q = x\,\Delta i_d - e \sin\delta\,\Delta\delta \tag{9}$$

where

x = tie-line reactance, the tie-line resistance is zero
e = infinite-bus voltage
δ = angle between the infinite bus voltage and the machine no-load voltage

The machine torque equation is:

$$\Delta T = i_{qo} G(p)\,\Delta E - (\psi_{do} + i_{qo} x_d(p))\,\Delta i_q + (\psi_{do} + i_{do} x_q)\,\Delta i_q + M p^2 \Delta\delta \tag{10}$$

where

M = moment of inertia of the machine rotor

If the possibility of using both a voltage and an angle regulator in combination is considered, the regulator equation becomes (see equation 7 of reference 7):

$$\Delta E = g_1(p)(e_d'\,\Delta e_d + e_q'\,\Delta e_q) + g_2(p)\,\Delta\delta \tag{11}$$

Using these equations and the relations 31 of reference 7 for the steady-state quantities under the given terminal conditions and with $x_d = x_q = x = 1.0$, the char-

Figure 6. Steady-state stability limit with angle regulator—effect of adding voltage regulator—synchronous machine and tie line

acteristic determinant of the coefficients is found to be:

$$p^{3}2MT_{a}(1+x_{d}')\cos^{2}\delta/2+p^{2}2M(2-g_{1}(p)\cos\delta/2)\cos^{2}\delta/2+p^{1}T_{a}\times[(1+x_{d}')\cos\delta+(1-x_{d}')\sin^{2}\delta]+p^{0}(2\cos\delta-g_{1}(p)\cos\delta/2+2g_{2}(p)\times\sin\delta\cos\delta/2) \quad (12)$$

If the angle regulator alone is considered

$$g_{2}(p)=\frac{a_{2}}{T_{r}p+1}$$

according to equation 1, and $g_1(p)=0$. Then the determinant becomes of the fourth degree in p when cleared of fractions. The limits of stability are determined by application of Routh's stability criteria[9] to this determinant for various operating angles δ and amplification factors a_2.

Performance Calculation of Induction-Type Frequency Converters

FREDERICK R. LATZKO
MEMBER AIEE

Synopsis: The performance of induction-type frequency converters is reviewed. A design method is given, based on the equivalent circuit. The current locus, with varying loads, is derived.

THE INTRODUCTION of high-speed motors for grinding spindles and for other industrial applications, on an ever increasing scale, brought with it an increased demand for induction-type frequency converters as a very practical solution for a source of high-frequency power supply. As the specifications vary considerably, in each individual case, a simple and reliable method for selecting and designing this type of equipment is important. The following analysis deals with frequency conversion, in general, above and below line frequency.

The Frequency Conversion

Figure 1(*A*) illustrates a simplified connection diagram of a frequency converter, for adjustable frequency, by means of a Ward-Leonard control. Figure 1(*B*) and (*C*) demonstrates the principle features of a converter, coupled to an a-c drive, providing single frequency only. It is beyond the scope of this paper to deal with all possible connection arrangements and their implications.

In its general construction, the frequency converter is identical with a standard slip-ring motor. With the primary winding connected to the available line, for instance, of 60 cycle, a voltage of line frequency can be measured across the secondary terminals at standstill (slip = 1). Driving the shaft of the frequency converter at some speed, either with rotation or against rotation of the revolving field, changes the voltage and frequency across the secondary terminals, as the relative speed of this field, in respect to the secondary winding, has changed. Frequency, and practically the voltage, also, are in direct proportion to this relative shaft speed, in other words, to the slip. The interrelationship between secondary frequency, shaft speed, and synchronous speed (=speed of revolving field), is graphically shown in Figure 2, and is given by:

$$\pm f_2/f_1 = \pm S \qquad (1)$$

$$n = [1 - (\pm S)]n_s \qquad (2)$$

For positive slips, larger than unity, the shaft speeds become negative, denoting a rotation against the revolving field. It may be noted that the phase sequence on the secondary terminals reverses in passing through synchronism. Disregarding the sign, a definite frequency always can be obtained at two different shaft speeds of the same converter, corresponding to a positive and to a negative slip of the same absolute value.

Paper 48-161, recommended by the AIEE rotating machinery committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, April 28–30, 1948. Manuscript submitted January 26, 1948; made available for printing March 18, 1948.

FREDERICK R. LATZKO is with the engineering department of the Electric Specialty Company, Stamford, Conn.

Selection of the Frequency Converter

The frequency converter must be selected in accordance with primary frequency, secondary frequency, shaft speed, and number of poles. These quantities are interrelated by the formula:

$$f_1 \mp f_2 = Pn/120 \qquad (3)$$

This function is plotted in Figure 3 for numbers of poles, from 2 to 20, and, for shaft speeds up to 4,800 rpm. The minus sign has to be used with positive slips and vice versa. For example, to obtain 420 cycle from a 60 cycle line, draw a line parallel to the abscissa, with $f_1 - f_2 = -360$ and with $f_1 + f_2 = 480$, and tabulate the values, on the abscissa, of all points of intersection, with the sloping lines:

Number of poles	20	18	16	14	12	10
Shaft speed ($f_1 - f_2 = -360$)	−2,160	−2,400	−2,700	−3,086	−3,600	−4,320
Shaft speed ($f_1 + f_2 = 480$)	2,880	3,200	3,600	4,114	4,800	

It is desirable to use the frequency converter with the smallest number of poles coupled directly to the driving motor. In the foregoing case, this condition is fulfilled with a 12-pole converter, driven at 3,600 rpm, against field rotation by a 2-pole motor. For an easy determination, whether direct coupling is feasible, Figure 3 shows, in heavier print, lines parallel to the abscissa, for the most common line frequencies of 60, 50, and 25 cycle. Their intersection, with the sloping lines, indicate the available shaft speeds for these frequencies.

Selection of the Driving Motor

It should be noted that an induction-type frequency converter may absorb or deliver power through its primary terminals, secondary terminals, and its shaft. The law of conservation of energy requires that the algebraic sum of all three powers, and of the losses of the converter

Figure 1. Simplified connection diagram

(A) for adjustable frequency
(B), (C) for single frequency

Figure 3. Chart for selecting frequency converters

itself, must be zero. The driving motor has to be selected in accordance with the mechanical power at the shaft of the converter, the accurate determination of which will be shown in connection with the design procedure. However, a general idea of the balance of the three powers may be obtained by considering an ideal converter without losses and without magnetizing current. For such a converter, the following equations apply:

$$P_1 = \pm(f_1/f_2)P_2 \tag{4}$$

$$P_{1M} = \pm(f_1/f_2)P_{2M} \tag{4a}$$

$$P_m = P_{2M} - P_{1M} = P_{2M}(1 \mp f_1/f_2) \tag{5}$$

$$P_m/P_{2M} = 1 \mp f_1/f_2 \tag{5a}$$

Figure 4 shows a graph of equation 5a. The ordinate from any point on the abscissa to either sloping line is a measure of the mechanical power at the shaft for the given ratio $\pm f_1/f_2$. It can be seen that operating at positive slips always gives smaller mechanical power (AB < AC A′B′ < B′C′). It can be shown that the two different mechanical powers, with which the identical secondary frequency may be obtained, are in direct proportion to the two different shaft speeds. For secondary frequencies, smaller than the primary frequency, $(f_1/f_2 > 1)$, and operating at a positive slip, the mechanical power becomes negative, which means that the converter delivers mechanical power to the driving motor, which in turn, becomes a generator feeding electrical power into the line. The larger mechanical power required, operating in the range of negative slip, is due to the fact that the primary power becomes negative (see equation 4 and 4a), feeding electric power into the primary line. Thence, primary and secondary power must be provided mechanically through the shaft.

Figure 2. Frequency-speed-slip diagram in per-unit values

$(N_s = 1, \quad f_1 = 1)$

The Performance of the Frequency Converter

It is well known that the frequency converter belongs to the category of the generalized a-c transformer. The current in the secondary reacts upon the primary exactly as in the case of the standard induction motor. One can actually consider the frequency converter as a slip ring motor compelled to run with a slip, $S = \pm f_2/f_1$, with an external impedance in series with the secondary winding. The current in the secondary winding develops a torque in interaction with the air gap flux. It is the task of the machine, mechanically connected to the shaft of the frequency converter, either to absorb this torque, or to overcome it, whichever the case may be.

Figure 5 shows the equivalent circuit of the frequency converter, which differs from the equivalent circuit of an induction motor only by the load impedance in series with the secondary circuit. It is convenient to calculate the constants of the converter for the primary frequency, f_1. The referring of the secondary constants r_2 and x_2, to the primary, is done in the same manner as in the case of an induction motor. Both resistance and reactance must be multiplied with an impedance reduction factor, a_g. In addition to it the resistance must be divided by the slip or, as an equivalent, multiplied with $a_F = \pm f_1/f_2$. The load impedance has to be established from the given secondary output conditions:

$$Z_L = \frac{m_2 E_2^2}{P_2} \tag{6}$$

$$r_L = Z_L \cos\theta_2 \tag{7}$$

$$X_L = Z_L \sin\theta_2 \tag{8}$$

The load resistance is referred to the primary by multiplying r_L with the same combined reduction factors, $a_F a_g$, as before. However, in referring the load reactance, it has to be noted that X_L in (8)

Figure 4 (left). Ratio of mechanical power to secondary power

Figure 5. Equivalent circuit

is given in terms of the secondary frequency f_2. It has first to be reduced to line frequency f_1 by multiplying it with f_1/f_2. This factor equals $|a_p|$, giving, for the load reactance, the combined reduction factor $|a_p a_2|$.

A clear conception of the general performance of an induction type frequency converter can be obtained by drawing the circle diagram of a fictitious induction motor with a rotor resistance $R_2 = r_2 + r_L$, and a rotor reactance $X_2 = x_2 + |a_p| X_L$ compelled to run at slips, $S = \pm f_2/f_1$. Figure 6 shows such a diagram. The two points, A and A′, represent the load points running at a slip $S = \pm 25/60 = \pm 0.417$, corresponding to a frequency conversion from 60 to 25 cycle. They were determined by means of the slip line. The interesting quantities can be read from the circle diagram in the same manner as in the case of a standard induction motor. The following tabulation may be helpful in understanding the performance:

Running at Positive Slip

AE—Total electric power absorbed through the primary terminals

AB—Mechanical power delivered at the shaft

BD—Electric power absorbed in the secondary circuit (secondary winding and load)

DE—Losses in primary circuit and core losses

Running at Negative Slip

A′E′—Electrical power delivered through the primary terminals

A′B′—Total mechanical power absorbed through the shaft

B′D′—Electric power absorbed in the secondary circuit (secondary winding and load)

D′E′—Losses in primary circuit and core losses

It may be noted that BD or B′D′ represent the total electric power absorbed in the secondary. Drawing a line, which intersects BD and B′D′ in the ratio r_2/r_L, permits the separation of the rotor copper losses BC or B′C′ from the useful secondary output CD or C′D′.

Any change in load represents a change in the value of the impedance Z_L, in series with the secondary winding. To find the new load points, would require to develop a new circle diagram, and again, to find on it the load points for $S = \pm 0.417$. In this way, one could develop, point by point, the current locus for changing loads. It is shown, in the Appendix, that this current locus is represented by a family of circles, each power factor load having a locus of two circles, one for $S = +f_2/f_1$, and one for $S = -f_2/f_1$. Common points of this family of circles can be found by solving the equivalent circuit, Figure 5, for $Z_L = \infty$, and $Z_L = 0$.

Design Procedure

The performance calculation will be explained in reference to the design sheet in Figure 7, which shows a complete sample design. As a first step, it will be possible, in most cases, to select a frame size, based on its rotor data, as a plain slip ring motor with due consideration to the actual frequency conditions. Assigning a suitable air gap flux, estimating the voltage regulation, and selecting the coil pitch, fixes completely the primary and secondary windings for a first trial design.

All the machine constants, based on line frequency, the no load current, core losses, and reduction factors, can then be calculated, and their values inserted in the proper places on the design sheet. The calculation of the load constants, based on secondary frequency, was described before. Line 1 to 9 gives the well-known calculation of the combined impedance of the equivalent circuit in Figure 5. The resulting primary current is calculated in line 10. The secondary current, in line 14, is calculated from the primary $EMF/_{1FL}$, acting on the total secondary impedance Z'_{2L}, expressed in actual secondary terms by dividing by a_l. The primary EMF_{1FL} is computed as the difference between the applied primary voltage E_1, and the drop $I_1 Z_1$, in lines 11 to 13, or by calculating I_1/Y_{2LM}. The secondary voltage, across the load, is calculated in line 15. The voltage regulation, in line 17, requires the knowledge of the *EMF*, under no load conditions. This calculation is performed in the same manner as before, for full load conditions introducing, in lines 18 to 21, the no load values rather than the full load values, or by calculating I_0/Y_m. It should be noted that the design started with an estimated voltage regulation, implying an estimated primary and secondary voltage drop.

As the actual voltage drop may differ from the estimated one, the values I_2, E_{2FL}, and P_2, in lines 14 to 16, may, on the first try, disagree with the specification. It may be, therefore, necessary to repeat the design with some other value, $\lambda Z_L = \lambda r_L + j\lambda X_L$, by multiplying the values in line 2 by λ, until a P_2—value is obtained close enough to the specified one. However, it may be that the values I_2, and E_{2FL}, with the correct P_2—value, may still differ from the specification. All that would be required, in this case, is to change the number of secondary turns in ratio of the desired full load voltage to the calculated one, provided the voltage regulation is satisfactory. If the latter is not the case, the voltage drop must be improved, which may necessitate the use of a larger frame.

As a last step in the performance calculation, the mechanical power, at the shaft, must be determined. For this purpose, the secondary watt output, and all the losses are added up, assigning to each item, the negative sign. (See lines 22 to

28.) In line 29, the primary watts are introduced with a positive sign, if absorbed, or a negative sign, if delivered. Line 30 gives the mechanical power as the algebraic sum of the values in lines 28 and 29. If the minus sign appears in line 30, the shaft of the converter has to be driven by a motor; if a plus sign appears, the shaft delivers mechanical energy which must be absorbed by a generator.

Appendix

Derivation of the Current Locus of a Frequency Converter, Loaded With a Constant Secondary Power Factor, by Changing the Load Impedance From Zero to Infinity

With reference to the equivalent circuit, Figure 5, the total secondary impedance is given by:

$$Z_{2L}' = Z_2' + \lambda Z_L' \tag{9}$$

λ is a real parameter which, in its most general form, may vary between $+\infty$ and $-\infty$

$$Y_{3m} = Y_m + 1/Z_{2L}' = \frac{(Y_m Z_2' + 1) + \lambda Y_m Z_L'}{Z_2' + \lambda Z_L'} \tag{10}$$

$$Z_{12} = Z_1 + 1/Y_{3m} = \frac{(Y_m Z_1 Z_2' + Z_1 + Z_2') + \lambda(Y_m Z_1 Z_L' + Z_L')}{(Y_m Z_2' + 1) + \lambda Y_m Z_L'} \tag{11}$$

$$I_1 = \frac{E_1}{Z_{12}} = E_1 \frac{(Y_m Z_2' + 1) + \lambda Y_m Z_L'}{(Y_m Z_1 Z_2' + Z_1 + Z_2') + \lambda(Y_m Z_1 Z_L' + Z_L')} \tag{12}$$

Equation 12 is of the form:

$$P = \frac{A + \lambda B}{C + \lambda D}$$

which is the equation of a circle in parametric form. The determination of the coordinates of the center point, and the radius, can be found in standard texts. For the considered load range, in which power is consumed by the load in the secondary circuit, the primary current follows the arc of the circle between the two points corresponding to $\lambda = 0$, and $\lambda = +\infty$.

List of Symbols*

r_1, r_2 = resistance in primary and secondary
x_1, x_2 = reactance in primary and secondary at f_1
g_m = conductance
b_m = susceptance
Y_m = admittance
} of magnetizing branch
r_L = resistance value of load
X_L = reactance value of load at f_2
Z_L = impedance value of load at f_2
Z_{2L}' = total secondary impedance referred to primary
Z_{12} = total impedance of the equivalent circuit
E_1, E_2 = phase voltages in primary and secondary
E_{20}, E_2 = secondary voltage at no load and at full load
EMF_{10}, EMF_{1FL} = primary electromotive force at no load and at full load
I_0, I_1 = primary current at no load and at full load
I_2 = secondary current
m_1, m_2 = number of phases in primary and secondary
N_1, N_2 = turns in series, per phase (primary and secondary)
K_{dp1}, K_{dp2} = combined distribution and pitch factor (primary and secondary)
a_E, a_F, a_I, a_Z = reduction factors for voltage, frequency, current, and impedance
n, n_s = shaft speed and synchronous speed in rpm
P_1, P_{1W} = primary power in volt-amperes or watts
P_2, P_{2W} = secondary power in volt-amperes or watts
P_m = mechanical power in watts
P = number of poles
$\cos\theta_0, \cos\theta_1$ = primary power factor at no load and at full load
$\cos\theta_2$ = secondary power factor
λ = real parameter

An Improved Design of Low-Voltage Panel-Mounted Air Circuit Breaker

LEON H. SPEROW
MEMBER AIEE

JOHN A. FAVRE
NONMEMBER AIEE

THE BASIC DESIGN of the general purpose low-voltage panel-mounted air circuit breaker has remained substantially unchanged for more than ten years. While the need for improvement has been recognized by the industry, the pressure of the war years has delayed this undertaking. The extraordinary demands of the armed services were usually outside the more familiar power and industrial requirements, and thus forced research and development that would ordinarily have spread over a longer interval.

Figure 1. 600-ampere manually operated, enclosed air circuit breaker

This work in a large measure was carried on by men who could recognize the value that much of their work would have in the commercial field. After the end of hostilities, no time was lost in starting a program of modernization to recover the losses from obsolescence of the war years. The principal accent was, of course, on performance, with reduced size and appearance running a close second. Appearance, or as it is better known, "the new look" could not be neglected either. This paper will describe in detail the features offered in the circuit breaker design which this program produced.

The New Circuit Breaker

Figures 1 and 2 show the new 225- and 600-ampere frame size air circuit breaker.

Figure 2. 225-ampere electrically operated air circuit breaker, for stationary switchboard mounting

The principal advantages offered in this design over older ones are specifically:

1. An improved arc chute of reduced size.
2. Long-lived contacts with momentary ratings equal to interrupting ratings.
3. Flexible and rugged overcurrent devices capable of necessary precision timing for selective tripping systems, but equally suitable for simple overload protection.
4. 30 per cent reduction in size—four circuit breakers in the space now occupied by three.
5. Longer life and lower maintenance from improved design.

Contacts and Interrupter

Figure 3 shows a section through one contact finger and part of the arc quencher construction. Two or more of these contact fingers are used for each pole and are separated by perforated phospho-asbestos arc barriers as shown. This design makes it possible to split the arc and quench three or four small arcs in a smaller space than an equivalent single arc requires. The holes in the barriers are of a size and number found to be necessary for arc transfer so that the interrupting job is equally divided. This is necessary to prevent the arc from concentrating in one slot or compartment. The contacts are faced with a sintered silver bearing, arc-resistant material admirably suited to the dual requirements that they efficiently conduct current and still resist the errosion associated with arc interruption. Their efficiency is attested by the fact that they have a momentary rating equal to their interrupting rating and that their resistance after arc interruptions of considerable magnitude shows little change. Much experimenting was done until this result was achieved, as the arc resistant components of many tip facings that were tested are inclined to collect at the surface

Paper 48-166, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28–30, 1948. Manuscript submitted February 16, 1948; made available for printing March 9, 1948.

LEON H. SPEROW and JOHN A. FAVRE are both with the air circuit breaker division of the General Electric Company, Philadelphia, Pa.

Figure 3. Contacts and interrupter

with attendant increase in resistance and heating. Inspection of Figure 3 will show the absence of heavy braids. The front or movable contacts are hinged on a close fitting preloaded silver plated pin, while the back or fixed contacts use a line contact pivot. It will also be observed that the fixed contacts with their supports form a reverse loop which increases the contact pressure under the action of high current. This feature is of considerable value as it permits lighter contact pressure, than is permissible without such a loop, which in turn reduces the wear on the contact and mechanism. Two things to avoid which may spoil an otherwise good contact design are bounce on closing and slow separation on opening. Bounce may be caused by any one of several factors, but must be suppressed. Oscillograms of these contacts show them to be quite free of this troublesome action.

Investigations made on contact wear indicate that life is increased by as much as three or four times if a contact opening of at least 40 mils is achieved in less than one millisecond when arcing is present. Adequate provision for wipe makes comparatively high opening speed easy in this design, as initial acceleration occurs before the contacts part.

The interrupter and contact structure has been thoroughly tested over the entire range of currents to establish the following interrupting ratings:

225-Ampere Frame Size	
600 Volts Alternating Current	15,000 Amperes
250 Volts Direct Current	15,000 Amperes

600-Ampere Frame Size	
600 Volts Alternating Current	25,000 Amperes
250 Volts Direct Current	25,000 Amperes

Figure 4 shows a typical oscillogram of a 3-phase 60-cycle, a-c interruption test made on the 600 ampere frame size circuit breaker. The average current of the three phases interrupted is 31,667 amperes at 590 volts and the total interrupting time is approximately one cycle.

This contact structure has proved capable of carrying 15,000 and 25,000 amperes for one second on the 225 and 600 ampere frame sizes respectively.

Overcurrent Tripping Devices

The familiar dual magnetic tripping devices relying on the adhesion of two mating disks in oil have served industry for many years. For most commercial applications in the past, they gave satisfactory service, but fundamental limitations became serious with the advent of selective tripping when more precise and reliable timing became a must. There are many varieties of timing devices, but they are all based on a very few fundamental principles as old as recorded history with the possible exception of some electronic methods. In approaching the design of the timing devices, there was no lack of material to choose from. The problem faced by the designer was more one of discriminating choice than the necessity of outright pioneering.

The new series overcurrent tripping device shown in Figure 5 is a three element device somewhat similar to the one used for several years on Navy circuit breakers, Figure 6. The new device has two armatures associated with a common magnetic circuit and series coil. One armature operates the long time and instantaneous elements, Figure 5*B*, the other, the short time element, Figure 5*A*.

The long time element is of the positive displacement type using silicone oil to minimize the effect of temperature change and avoid sludging. The unit is hermetically sealed to prevent contamination. The piston carries a fixed orifice of a size suitable for the time-current characteristic desired.

The top left portion of Figure 7, above *C*, is representative of the characteristic and is shown as a solid band rather than a single line curve. The top limit represents the maximum time including variations of the device and the maximum in-

Figure 5. A 2-armature 3-element overcurrent tripping device

terrupting time of the circuit breaker. The bottom limerit presents the minimum tripping time including variations. Below the band is a dotted curve of reset time defined as the maximum time that the device will carry a given value of current, then reset when the current is reduced to a given percentage (80 per cent for the long-time curves) of the pickup setting. Standard pickup settings are 80 to 160 per cent of the coil rating and may be set by adjusting the scale plate on the front of the device. Setting this scale plate varies the restraining force on the armature.

The armature for the long-time element is connected to the piston by means of a heavy spring, which provides the instantaneous feature of the device. This permits the instantaneous element to be set in the factory to any required value up to 100 times coil rating. However, in a few cases, the momentary rating of the circuit breaker or the amount of delay to be employed may impose limitations on this setting.

The short time armature operates an escapement type of timing mechanism, Figure 5*A*, which produces an inverse time current characteristic. The escapement wheel is made with teeth only on part of its periphery, thus, the delay is set by varying the position in the stroke of the armature at which the escapement wheel runs free of the pallets.

Since the function of the short time element is to give short delays in the fault current range, pickup settings are from five to ten times coil rating. The upper and lower limit of the time current characteristics are similar to the long-time characteristics except that the reset time is based on the fault current reducing to 20 per cent of the pickup setting. The middle portion of the solid band in Figure 7, between *A* and *B*, is a typical time-current characteristic.

Figure 6. A single-armature 3-element overcurrent tripping device

The three elements of this overcurrent tripping device have been designed to be combined in any way desired. Standard combinations are:

Instantaneous, high set and nonadjustable
Instantaneous, low set and adjustable
Long time and instantaneous
Short time and instantaneous
Long time, short time and instantaneous

A combined time-current characteristic of a device having all three elements is shown by the solid band in Figure 7 and for one having only long time and instantaneous by the shaded band. In the case of the solid band, the adjoining portions of the different characteristics are produced by separate armatures, thus the sharp intersections at *A* and *B*. However, for the shaded band, both portions of the characteristics are produced by the same armature and their intersection is rounded out as at *C*. Thus for a single armature device (Figure 6) or one in which the timing elements do not function independent of one another, the intersections will be rounded as of *C*.

Reduction in Size

The advantages of reduced size, as shown by Figures 1 and 2 were achieved, in part, by careful design calculated to make the most of smaller elements used as auxiliaries. The operating solenoid was designed carefully to produce the maximum performance from iron and copper. A new control was designed which is inherently antipump and so on down the line with the result that space reduction was achieved with no loss of any function usually associated with circuit breaker control. The reduction in size has not only been reflected in the new circuit breakers themselves, but also in the switchgear equipments using them. For example, the drawout switchgear equipment in Figure 8 has 600-ampere circuit breakers stacked four high in each unit. Previous designs would accommodate only three per unit. The new drawout equipment has each circuit breaker assembled into a steel truck fitted with free running rollers and rack-out mechanism which make the removable element easy to insert or withdraw.

Sturdy primary disconnecting contacts of a design capable of handling momentary current in excess of the circuit breaker interrupting rating assure dependable cascade operation. Secondary disconnects have been reduced in size so that as many as 28 points per circuit breaker are available for connecting auxiliary and control devices.

Figure 7. Typical time-current characteristic of the 2-armature 3-element overcurrent tripping device

Maintenance

Longer life and lower maintenance are also products of good design. For many years ebony asbestos, masonite die stock, laminated phenolics and similar materials have been used for air circuit breaker mounting bases. While they showed an improvement over the old slate panels, a still better base was necessary. The advantages of a composite aluminum and steel base supporting separate molded base units become more obvious as this

Figure 8. Drawout switchgear equipment using the new 225- and 600-ampere air circuit breakers

arrangement is discussed. The low-unit strength of former panel materials of necessity made them cumbersome for both mechanical and electrical reasons. The use of molded components permits reduction in size and improved strength as creepage is readily maintained by barriers and strength can be secured without useless bulk. The metal base is of considerable value in reducing the fire hazard as this metal base separates the bus compartment of a switchboard from circuit breaker compartments so that faults cannot readily communicate between them. One important contribution of the plastics industry during the war was an asbestos rag-filled phenolic with very high impact strength and good arc resistance. Liberal use of this and cotton-filled plastic is characteristic of this circuit breaker and is in keeping with the plastic era which seems to be a mark of the times. The versatility and usefulness of plastics for both mechanical and electrical reasons is well known to all, but in passing, it might be pointed out that original finish and appearance lasts for the life of the device.

This circuit breaker features a trip shaft carried in two sealed antifriction bearings which should never require attention because of sticking. The latch itself bears on a similar bearing. The operating linkage is fabricated from alloy steel and bronze and is lubricated with an extreme temperature lubricant of high staying power. The contacts are operated through plastic links so that we have a dead front circuit breaker with overcurrent tripping devices that can be adjusted if necessary while energized. Operating solenoid, trip units, and contacts are readily accessible, or replaceable from the front. Most of the components are the same in both circuit breakers so that spare parts inventories are kept to a minimum. The maintenance problem is simplified further because nearly all of the accessories are designed so that they may be precalibrated as a complete unit, then assembled to the circuit breaker without further test. The accessories are designed for removal from the front of the circuit breaker thus simplifying the maintenance of those circuit breakers which cannot be removed to a bench.

Summary

Close co-operation with the Navy during the war in working out solutions for rapid improvement of pre-war standards of protection and control of low-voltage distribution circuits, gave the group that developed these circuit breakers an enviable background of experience to fit them for the program just discussed. The results of their efforts have been outlined and can be summarized by saying that industry is offered a new circuit breaker in which high inrush and momentary currents are easily handled, with an increased contact life.

Accurate and proved timing elements have been provided giving a variety of desired time-current characteristics.

A wider application on motor and other repetitive duty high inrush current circuits is assured by longer contact and mechanism life and accurate delayed tripping obtained with the fluid displacement timing elements.

Dependable selective operation can be obtained without the additional expense of current transformers and relays.

Contacts and coils which will stand the high momentary currents, while tripping is delayed with an accurate mechanical timing device, make possible dependable selective operation, so unquestionably proved on the Navy's major ships.

Discussion

M. E. Horn (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors are to be congratulated on their presentation of the performance requirements of low-voltage air circuit breakers. It may not be known generally that the admirable degree to which circuit breaker designs were produced to meet armed service requirements was made possible by the pooling of ideas and research information on an industry-wide basis. It is believed that the authors will readily agree that even a majority of the contributions to the art of circuit breaker design in the war period could not be attributed to any one manufacturer. Consequently, new commercial designs now reaching the market are likely to show marked similarity in improved operating characteristics.

With reference to statements in the paper regarding the reduction in space required for mounting the new circuit breaker and Figure 8 showing four unit high drawout gear, additional amplifying statements by the authors may be in order. In view of the fact that at least one manufacturer has been offering drawout or fixed mounted gear of this same rating in four unit sections 90 inches high for the past eight years or longer, the question naturally arises as to the height of the switchboard sections shown in Figure 8. In this presentation, the authors have exhibited considerable knowledge of the problems related to contact design, and their frank discussion leaves the impression that the new contacts will have an exceptionally long operating life. It is further noted that Figure 3 does not show the contact tips to be renewable. It is assumed, therefore, that to renew the moving contact considerable disassembly of the circuit breaker is involved. Should it also be assumed that contact life approached the life of other circuit breaker parts and that contact renewal is contemplated only as a major overhauling operation? The matter would be considerably clarified by a statement by the author concerning the expected contact life, particularly on circuits involving considerable stored energy, such as may be encountered on 250 volt d-c circuits to which the circuit breaker is applicable or on a-c motor starting applications.

The series overcurrent tripping device is shown with considerable detail by Figure 5. It appears that the linkage operating the long time delay plunger enters the fluid compartment through a bearing shaft arrangement. A screwed-on cover is also indicated for the fluid compartment. However, the statement is noted: "The unit is hermetically sealed to prevent contamination." Inasmuch as Webster defines the term "hermetically sealed" as "sealed by fusion" the question arises as to how this seal by fusion could actually be performed with functional parts arranged as per Figure 5.

Leon H. Sperow and **John A. Favre**: The performance specifications for the Navy circuit breakers on which this new design is based were determined by requirements of the armed services as pointed out by the authors. Undoubtedly many of the items of these specifications were the result of suggestions by various manufacturers.

However, the devices used on this new line of circuit breakers are ones which were developed by the authors' company.

The statements in the paper regarding the size of the new circuit breaker were directed primarily at previous designs with which the authors have had direct experience. In the case of the earlier designs, only the 225-ampere frame-size circuit breaker could be supplied in four-unit drawout mounted gear of 90-inch height. With the new design both the 225- and the 600-ampere frame size can be furnished in four-unit sections, 90 inches high and 20 inches wide.

Contact life on both interrupting and closing duty has been greatly increased over that of previous designs. Tests on high inrush currents such as encountered on a-c motor-starting applications show, for example, that the contacts of the 600-ampere frame size circuit breaker will last more than 2,500 operations at 4,000 amperes.

Reference to Figure 3 will show that both the movable and stationary contact fingers are relatively small parts. Their design is such that the complete fingers may be economically replaced in the field whenever it becomes necessary. The replacement can be readily achieved since the subassemblies have been designed for easy removal from the front of the circuit breaker.

The authors used the term "hermetically sealed" in its more common sense, that is, "completely sealed by any means." The top of the cylinder is sealed by a cemented and gasketed screwed-on cover. The bearing and shaft arrangement is completely sealed by a synthetic rubber sleeve which is cemented and clamped around the shaft and bearing.

A New Isolated-Phase Metal-Enclosed Bus Designed for High-Capacity Generating Stations

B. W. WYMAN
MEMBER AIEE

R. B. SHORES
ASSOCIATE AIEE

THE design of bus runs for high-capacity generating stations has always received considerable attention in order to insure freedom from faults of any type, whether due to insulation deterioration, insulation contamination, mechanical failures, or other causes. With greater concentrations of generating capacity in single stations, short-circuit currents have steadily increased and the damage resulting from bus faults has steadily become more serious, so that constantly greater reliability has been sought in station bus design. In addition, many power systems are now operating with very low reserve capacity so that bus faults which might cause the loss of any station or part of a station, even for short periods, must be guarded against. This paper describes the development of a metal-enclosed isolated-phase bus for generating stations, which combines a high degree of reliability with immediate accessibility for inspection or maintenance.

Background

Early designers of station bus realized that the short-circuit current in phase-to-ground faults could be limited by neutral impedance, whereas phase-to-phase faults could not, so their attention was directed toward station layouts which would prevent phase-to-ground faults from developing into phase-to-phase faults. Some of the first attempts to eliminate phase-to-phase faults resulted in concrete barriers being constructed between phases. This construction, while an improvement in reducing the frequency of phase-to-phase faults, was difficult to keep free from contamination or rodents, and some operators felt it actually increased the frequency of phase-to-ground faults. It also left much to be desired both in safety to personnel and in ease in extending or relocating. Even greater freedom from phase-to-phase faults was attained in some cases by locating each phase on a separate floor. As each circuit breaker phase then had to be located on a separate floor, extremely awkward and bulky station layouts resulted. This idea was abandoned in favor of metal-enclosed bus runs with each phase conductor completely insulated by Herkolite or compound, but with all in a common metal enclosure. The compactness of this type of bus together with its ease of installation and safety to personnel has ideally suited it to all metal enclosed switchgear in which fault magnitudes do not exceed 500,000 kva. Compound supports are normally used in this construction to support the insulated conductors. The upper section of Figure 1*a* shows a cross section of this type of nonsegregated phase which has become standard for many of the smaller industrial plants and generating stations.

For large generating stations, on the other hand, where short circuit magnitudes may exceed 500,000 kva, and where load currents run into several thousand amperes, it has normally been necessary to resort to tubular or channel busses, both to carry the high load currents and to withstand the magnetic forces encountered during short circuit. As wrapped or pressed-on insulation for this type of bus is economically impractical, it has been customary to use only air insulation and to support the channel conductors on porcelain insulators. To prevent phase-to-phase faults with this construction, the phase conductors were then spaced far enough apart so that metal barriers could be located between phases as shown schematically in Figure 1*b*. This

Figure 1. Schematic comparison between different types of metal enclosed bus

A. Nonsegregated phase in common metal enclosure with flat bar conductors insulated by compound

B. Segregated phase bus with all three channel conductors insulated by air and in common metal enclosures with metal barriers between phases to prevent phase-to-ground faults from developing into phase-to-phase faults

C. Isolated phase bus with each channel conductor insulated by air with each conductor in its own metal enclosure, thereby providing two metal barriers between phases for greatest security against phase-to-ground faults developing into phase-to-phase faults

Paper 48-169, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28–30, 1948. Manuscript submitted February 24, 1948; made available for printing March 23, 1948.

B. W. Wyman and R. B. Shores are both with the General Electric Company, Philadelphia, Pa.

Figure 2. Actual station circuit breaker layout using earlier design of isolated phase bus up to 5,000 ampere ratings and high capacity station type air blast circuit breakers rated up to 2,500,000 kva

segregated phase construction is in use in a large percentage of the higher capacity generating stations throughout the country.

The reliability of the metal barrier between phases in eliminating phase-to-phase faults has been demonstrated by the thousands of circuit years operating experience without outage. Most of these segregated phase bus installations have been ventilated by louvers so that the minimum cross-section conductors could be used without overheating. Because of the extreme importance of service continuity on all equipment at the present time connected to these busses, many operating engineers are now specifying dust-tight enclosures without louvers to guard against dust depositing on insulator surfaces.

It has been realized for years, however, that one of the weaker points of the segregated phase construction was the possibility of the phase-to-ground arc burning through one of the metal interphase barriers, and thereby developing into a phase-to-phase fault, or double phase-to-ground fault. Although the possibility of the barrier burning through is remote if the fault arc is interrupted quickly, it does become more likely if the fault current is left on an appreciable length of time, or if the current magnitude is high. The possibility of an arc burning through such a metal barrier is greater in the bus sections connected directly to the generator terminals ahead of the first circuit breakers because of the time interval required for the fault current to decay to zero.

Tests have shown that protection can be obtained against such a burn-through if each phase conductor is enclosed in its own nonventilated metal enclosure and the three enclosures are then separated by air spaces. With this arrangement, even though an arc burns through the side of one enclosure, ionized gases cannot get into adjacent enclosures. Several different designs of bus with each phase bus conductor in its own enclosure have been installed in the past several years in which the basic idea of air separation between the metal enclosures has been proved sound. Figure 1*c* shows schematically this isolated phase construction.

Figure 2 shows the layout of a large modern generating station, and Figure 3 is a view inside the station showing one design of isolated phase bus connected to some 5,000-amperes 2,500,000-kva station-type air blast circuit breakers.

After reviewing existing designs of busses it was decided to undertake the development of a completely new bus type which would afford a high degree of reliability with immediate accessibility for inspection and maintenance, and also provide maximum ease of installation by designing for complete factory assembly to reduce the amount of work necessary in the field. By questioning operating engineers, construction engineers, and consulting engineers, a set of specifications was established to guide the development of the new design.

Requirements for New Design

The following set of specifications was set up as requirements for the new design:

1. Ultimate design must permit shipment of complete factory assembled sections to reduce field installation time to a minimum.

2. Designs must permit maximum accessibility for inspection or maintenance so that

Figure 3. Earlier type 5,000-ampere isolated-phase bus being installed in station layout shown by Figure 2. The 2,500,000 kva air blast circuit breaker is in the background

Figure 4. Single phase section of new type isolated phase bus to provide greater reliability for high capacity generating stations

Cover in closed position showing unusually clean appearance due to square enclosure without protruding bolts or screwheads. This section would constitute an individual phase shipping unit for easy installation in field

Figure 5. Single-phase section of new type isolated-phase bus with cover open showing ready accessibility to bus for inspection or replacement of any part

This section is rated 4,000 amperes continuous current with momentary short-circuit current rating of 130,000 amperes

any insulator, or bus section could be inspected, or even removed and replaced, in the shortest possible time. As some busses will be installed in hazardous locations (such as on scaffolding or suspended from ceilings) unbolting or handling of heavy, loose covers should be avoided by hinging them.

3. The number of porcelain insulators should be kept to a minimum consistent with strength requirements in order to reduce the number of creepage surfaces, as each unnecessary creepage surface constitutes a potential flashover point.

4. Angular and longitudinal flexibility should be designed into the bus and enclosure junctions so that no high accuracy alignment is necessary in the field which will increase the cost of installation.

5. Longitudinal flexibility should be designed into the bus junctions to provide for thermal expansion and contraction of long runs without introducing strains in either bus supports or porcelain insulators.

6. The metal enclosures should be dust-tight to prevent dust, moisture or other contamination from entering the enclosure, which might reduce the flashover strength over insulator surfaces. This would eliminate the necessity of porcelain cleaning which has always been necessary on ventilated enclosures. In addition, it would not permit the entrance of ionized gas from an arc into an adjacent phase even if that arc burned through its own enclosure.

7. The metal enclosures should be weather-tight so that they can be installed either indoors or outdoors without special construction or additional installation precautions.

8. Temperature rise limitations, 60-cycle high-potential withstand tests, and basic-

Figure 6. End view of isolated-phase bus showing manner in which 4,000 amperes channel conductor is supported by standard porcelain insulators, with provision in conductor support for thermal expansion or contraction of conductor by slide fit

Porcelains are supported on heavy removable brackets which in turn are bolted to supporting pads. These pads are rigidly fastened through the enclosure to the H-beam cross member

impulse withstand tests must be in accordance with AIEE Standards for station-type switchgear.

9. A generous margin of mechanical strength should be designed into the bus supports to withstand the maximum magnetic forces associated with the rated momentary short-circuit currents.

10. Metal enclosures should be constructed of nonmagnetic material to eliminate magnetic heating and thereby permit minimum cross-section conductors.

11. Seal-off bushings should be provided at appropriate locations to act as arc and gas barriers in order to prevent the possibility of a phase-to-ground arc within an enclosure running along the entire bus length.

Design of New Isolated Phase Bus

Figure 4 shows a 4,000-ampere single-phase section of the new isolated phase bus with the cover closed. Figure 5 is this same section with the cover opened, showing the complete accessibility to the bus which is possible when the cover is open. The design of the enclosure consists essentially of a single aluminum sheet shaped to form three of the sides, while the fourth side consists of a gasketed cover. The square configuration with no screws and bolts projecting through the surfaces results in an exceedingly clean attractive appearance. The cover is hinged on either side so that it may be swung open to inspect or replace any part after merely loosening clamping bolts. The channel bus is supported on standard porcelain insulators which are normally carried in stock in all power stations at the present time. Silver surfaced semiflexible copper connections are used to connect the end of each channel section to the next section, thereby providing angular flexibility as well as providing for thermal expansion and contraction of the bus. The porcelain insulators supporting the bus are in turn mounted on removable heavy steel supporting brackets as shown in Figure 6. These removable brackets are in turn bolted to two sturdy feet. Any insulator may, therefore, be removed or replaced at

Figure 8. Close-up view showing split banding ring which clamps over gasketed circular flanges of adjacent end plates

These banding rings between housing sections provide angular and longitudinal tolerance for ease of installation. These bands also permit standardization of housing lengths by varying the width of the banding rings and flexible copper connections to suit individual installations

Figure 7. Three-phase assembly of the new isolated-phase bus

This unit consists of three individual phase housings suspended from two H-beam cross members which constitutes a 3-phase shipping section

Figure 9. Two 8-foot development sections assembled for 110-kv impulse withstand test with covers removed from center phase to show bus

Figure 10. A 4,000-ampere development sample bus section set up in high-capacity short-circuit testing station for short-circuit tests up to 200,000 amperes

will. The steel supporting feet are bolted solidly through the housing to the main *H* beam which carries all three phases. The details of this construction are shown in Figure 7.

Each end of the housing fits into the gasketed groove of an aluminum end plate. A circular flange with an insulating gasket around its circumference projects from these end plates. Simple split aluminum banding rings are then used to span the distance between the end plates of adjacent sections. When tightened up, these aluminum banding rings clamp down on the gaskets to exclude any possibility of dust entrance, as may be seen in Figure 8. These gaskets provide insulation between each section of the housing to eliminate the flow of circulating currents. The length of these banding rings can be varied at will so that most bus sections in a given length of bus run can be a standard uniform length which is ideal for both manufacture and installation. A heavy continuous longitudinal ground bus extends the full length of the bus run and is connected to each section. Insulation spacers are provided between metal housings and H-beam cross members as necessary to break up stray circulating current paths which could cause overheating.

All gaskets have been selected to make the sections both dust-tight and weather-tight so that the same construction is used for either indoor or outdoor service. In order to test the tightness of the unit against dust, a section of bus was located in a sandblast enclosure for some time where the dust was so dense that it was impossible to see more than a few feet. To test its weather tightness, a high-pressure spray from a nozzle was directed on the gasketed joints demonstrating the ability of the gasketed enclosure to keep moisture out.

Tests on Isolated Phase Bus

After successfully completing both 60-cycle high-potential test and impulse withstand tests, heat runs on the various ampere ratings were made to be sure that no ratings exceeded more than 45 degrees centigrade rise on the conductor and 30 degrees centigrade rise on the enclosure. An extensive series of short-circuit tests were then made to determine whether the unit would withstand the magnetic forces associated with the maximum momentary current rating of the bus. Figure 9 shows a 2-section development test unit being prepared for 110-kv impulse withstand tests. Both center phase sections have their covers removed to show the channel bus and supporting insulators.

Figure 10 shows these test sections connected for test and located on the test car inside a test cell in the high-current short-circuit laboratory. A total of 69 short-circuit tests were made at varying currents and with various types of faults (both phase-to-ground and phase-to-phase, up to 200,000 amperes) which exceeds the momentary rating for any of the various ratings of busses. Figure 11 shows schematically representative tests of this series. The porcelains are loaded differently in different types of faults. In test 39, at the top of Figure 11, is a phase-to-phase fault test of 200,000 amperes, which repels the 2-phase conductors, places the two outside insulators in compression and the two inside ones in tension. When the bus had withstood all possible types of faults without damage, the porcelains on one side of the bus were removed and the tests repeated. Tests 43, 51, and 61 are examples of these tests. Although this placed a double load on the remaining insulators, close inspection still revealed no damage to any parts. These latter tests, with half the insulators removed, probably represented much more severe conditions than would ever be required in service. However, it was felt that with the high degree of reliability required of this type bus in service, this extra margin was desirable rather than using lighter porcelains which probably could have been done.

Installation of Bus

The complete assembly of the bus in the factory reduces installation time to a minimum. The bus can be shipped either as individual phase sections or 3-phase sections, depending upon which happens to be the most convenient. As the entire enclosure is made of aluminum, the weight is kept to a minimum for easy handling. The flexibility between the various sections of both bus and enclosure eliminates the necessity for any accurate alignment or location of one section with respect to another, which greatly reduces the cost of installing this type of bus over previous designs. As blank end plates or banding ring end plates are interchangeable, later extensions, side tap-off additions, or rearrangements can be made in a minimum of time. Figure 12 shows an actual station plan using this new type of isolated phase bus in a unit generation steam station, running from the generator terminal inside the plant to the three single-phase step-up transformers outside the building, and to one 3-phase station service transformer.

TEST NO.	SET UP	AMPERES (RMS. FULLY OFFSET)
39	PHASE TO PHASE	200,000
43	 PHASE TO PHASE	140,000
51	 PHASE TO PHASE	191,000
56	PHASE TO GROUND (HOUSING RETURN)	200,000
61	 PHASE TO GROUND (HOUSING RETURN)	174,000
69	 PHASE TO PHASE	200,000

Figure 11 (left). Typical momentary short-circuit current tests on a sample section of the new isolated-phase bus run rated 15-kv 4,000-amperes continuous with momentary rating of 130,000 amperes

A portion of the 69 tests conducted on this sample section were made with the deliberate removal of half the porcelain insulators in order to prove the design of the individual supporting brackets. At the conclusion of this set of tests, no damage had been incurred to any parts of the bus run

Figure 12. Typical station layout of unit generation scheme showing new type isolated-phase bus connecting from generator to disconnecting switches to three out-door single-phase step-up power transformers and a 3-phase station service transformer

The same construction is used for both indoor and outdoor portions of bus. Potential transformers and surge protection equipment are located inside station connected by a tap-off from the main bus

The connections between the conductors of a metal enclosed bus and the terminal bushings of a generator or power transformer are made by means of flexible braid to prevent any misalignment or thermal expansion strain being placed on such bushings. It is usually possible to maintain a high insulation level in the housing for transformer terminals, but the close spacing of some generator terminals occasionally makes it difficult to retain the full 110-kv impulse withstand when it is necessary to carry the isolation of phases to the generator terminals.

Provision is made for spanning the joint between the generator foundation and the building proper with a flexible connection in both the housing and the conductor.

Conclusions

The isolated phase bus design described in this paper fulfills all of the stated requirements for high-capacity generating station bus. It is proving very flexible in application, and its installation is relatively simple. Tests have proved that it will meet its rating with a generous design margin. It is believed that this development has resulted in a bus for high-capacity generating stations and large industrial plants which will afford a high degree of reliability with immediate accessibility for inspection and maintenance.

Discussion

P. R. Pierson (Westinghouse Electric Corporation, East Pittsburgh, Pa.): The authors have prepared a very interesting presentation of isolated-phase metal enclosed bus for high-capacity generating stations. A new design is offered which has many desirable features for those applications having exceptionally heavy duty requirements. The subject has been carefully studied and a good background of test data has been provided.

The statement that most of the segregated phase bus installations have been ventilated by louvers does not apply to at least one large manufacturer of this type of bus. Their applications have been of nonventilated construction except for a few special applications. Even though inspection covers are not gasketed, experience has demonstrated that dust accumulations are considerably less than in those where intentional ventilation is provided. The result is longer intervals between maintenance periods and less likelihood of interchange of gases between phases.

The authors point out that one of the

weaker points of segregated phase construction is the possibility of phase-to-ground arcs burning through one of the metal barriers. Tests made on similar structures, constructed of 1/8-inch thick steel, nonmagnetic steel and copper alloy at various current ratings, indicate that the hazard from this is relatively slight. On currents as high as 60,000 amperes enduring for 23 cycles, no punctures occurred in separating barriers. Fault tests within the enclosure at full voltage are important to the design of such structures, as the amount of gas created introduces problems which the authors apparently have not considered.

In their discussion on installation, the authors point out the flexibility between various sections of both the bus and the enclosure. The flexible joints in the bus at each section undoubtedly provide this. However, it is not at all apparent how this flexibility exists between the enclosures. They are coupled by a relatively short clamping ring which has to fit tightly to give an air-tight construction. This would mean that accurate alignment of the enclosures was almost a necessity.

Another thought on these bus structures, which merits consideration, is an arrangement by which the housings could be put up and the busses put into them. This would mean that long lengths of bus could be used in many cases and a great number of joints eliminated. A reduction in the number of joints is always desirable and consideration of this problem has indicated that such an installation is possible and at no sacrifice in total installation cost.

R. B. Shores: The discussion presented by Pierson is appreciated as it presents several design features of the new bus which were not accounted for in sufficient detail in the paper.

The quantity of louvers, or deliberate perforations of some type, in existing designs of bus runs can frequently be decreased and even eliminated by increasing the size of the conductor. However, deliberate perforations for ventilation do not represent the total openings in housings constructed of nongasketed metal plates, and the amount of dust deposited on insulators in such housings becomes a matter of degree. The new design is definitely differentiated from a ventilated line of bus enclosures by having all joints in the enclosure made dust-tight by means of gaskets.

We agree with Pierson that fault tests within enclosures are important in the establishment of designs. Field experience, as well as tests made in the high-current laboratory to investigate what happens when an arc-to-ground does occur on a bare bus inside an enclosure, have indicated that an arc travels very quickly along the bus to a barrier, or corner, and does little burning along the length of bus traversed. However, unless interrupted within a matter of cycles, the arc will burn through the housing at a point where it tends to hang. It is true that the amount of gas created in the enclosure is a major problem, and unless the arc is of very low magnitude or unless the arc is interrupted very quickly, no metal enclosure of any shape or practical thickness is going to contain the fault. Since the gas pressure is on all walls of the enclosure, there is as equal a chance on a single line-to-ground fault of the interphase wall giving way as of the outside wall.

In designing the new bus, it was felt that no attempt should be made to hold this pressure to the point of rupture of the housing, which might result in injury to personnel or damage to adjacent equipment by flying metal covers. It has been shown by actual tests that the new design, which uses hinged covers held on by lugs instead of through-bolts, will relieve internal pressures by bowing out of the center of the housing sufficiently to permit the center of the cover to slip from under the lugs and itself bow up; however, the covers in all tests were retained by the hinges and lugs at the cover ends. After each internal fault test, the enclosure sides were straightened in place, and the covers removed, straightened, and replaced. In each internal fault test the arc moving along the bus produced a traveling pressure wave subjecting the entire length of the test run to internal pressure.

The circular flange of each housing end plate has a recessed groove into which a gasket of circular cross section fits. The banding ring and circular cross-section gasket permits axial and angular misalignment of the housing; the length of the banding rings, together with the designed clearance between the circular flanges of the connected end plates and the designed clearance between the banding rings and flat surfaces of the end plates, permits longitudinal variation in spaces between individual housings.

The most important length of conductor within a station is usually the main bus directly connecting together a group of power circuit breakers, yet in a modern installation of factory-assembled metal-enclosed circuit-breaker units this main bus actually consists of short sections, each approximately the width of the circuit-breaker unit, connected together with some type of splice plate. This fact eliminates any hesitancy in the use of short conductor sections. However, there is a very great advantage in the use of short sections of conductor from the standpoint of provision for expansion and ease of alignment, especially in the use of heavy tubular or channel shaped conductors. The alignment of two conductor supporting stations per length of conductor is a relatively simple matter in comparison to the use of three or more supporting stations since supporting stations must be sufficiently aligned to permit slip of the conductor for thermal expansion or contraction and yet not loose to the point of rattle (which would also result in impact stresses on the porcelains on high momentary currents). The alignment problem of more than two stations is also complicated by the fact that copper shapes are not exact in size and true in straightness. In addition to simplifying the alignment problem and of permitting factory-assembled sections to be shipped with the conductor in place, the use of short sections permits ready removal or insertion of any copper conductor after installation of the housings if necessary.

Circuit Breaker Modernization and Faster Fault Clearing on Single-Phase Electrified Railroad

Synopsis: The circuit breakers designed in 1913 for sectionalizing the 11/22 kv 3-wire trolley and feeder circuits on the New Haven Railroad electrification had become inadequate by 1936 because of limited interrupting capacity to clear line faults fast enough to insure system stability and reliability. Although these were never designed to handle the entire fault interrupting duty, space and weight limitations in the switching stations and supporting structures ruled out their replacement with modern circuit breakers of conventional design adequate for faster fault clearing. The application of modern interrupters to the original circuit breakers, together with the redesign of tanks, operating mechanism and supporting frames (with spring supports), produced a circuit breaker of approximately the same over-all dimensions and weight which by high-power laboratory tests proved to be adequate to interrupt the entire fault current (instantaneous rms symmetrical) as determined by a-c network calculator studies of the system. These studies were also the basis of application of instantaneous overcurrent relays for fault clearing by the line circuit breakers, of which there are over 500, making this system one of the largest installations with this type of relay protection. An analysis of the network calculator studies, the tests of the redesigned circuit breaker, and the operating results with their application are here reported.

The Railroad Sectionalizing and Original Fault Clearing Scheme

THE 11/22 kv 3-wire system of power transmission and distribution for the single-phase a-c electrification of the New York, New Haven and Hartford Railroad between New York and New Haven, Conn., was placed in service in 1914, seven years after the initial a-c electric operation, and has been described in more detail in a recent Institute paper.[1] There are over 200 separate sections of through trolley and feeder circuits protected at each end, together with about 50 radial or stub-end trolley circuits, and 100 bus and tie circuits, all protected by approximately 525 outdoor oil circuit breakers of special design. The 4-track line is sectionalized at interlocking and track switching points where signal towers are located. The circuit breakers were designed to be mounted directly over the tracks and trolley system, on the adjacent catenary anchor bridges, which were specially designed to carry this equipment, see Figure 1.

These bridge-type circuit breakers, so called because of their location, had an interrupting capacity of about 3,000 amperes at 11 kv, and the associated relay system was so designed that no line circuit breaker was opened under fault conditions until the fault current had been reduced to a safe interrupting value (between 2,500 and 3,000 amperes) by the automatic insertion of resistance in series with the line at the power supply points. The insertion of these resistances, which were of values several times the maximum line impedance, had the effect of greatly reducing the fault currents. In all through parallel circuits, except the faulted circuit, the reduced fault currents approached nearly uniform values below the pick-up setting of the type *B*, over-current, line circuit breaker relays. This permitted all the relays which picked up on the initial high values of fault current, except those controlling the one or two circuit breakers directly feeding the fault, to drop back during the interval between the instant of fault and the energization of a common trip-power circuit from the power station to all switching stations. Any relay remaining picked up would then allow its associated circuit breaker to be tripped from this trip-power circuit.

The resistance was inserted in both the trolley and feeder circuits at the power supply points by a main over-current relay of special design, manually adjustable in its setting, which was kept slightly greater than the maximum expected load swing. This relay picked up on faults and caused a by-pass circuit breaker to open, which normally short circuited the resistance, always in series with the line. An auxiliary "*b*" switch on this by-pass circuit breaker energized the closing coil of a circuit breaker which energized the 11-kv automatic control wire. This furnished tripping power through small 11,000/110 volt transformers at all anchor bridge switching stations (see Figure 2). The bridge circuit breakers were thus tripped by 110-volt 25-cycle alternating current. They were reclosed by 110-volt 25-cycle alternating current from another circuit, normally energized. In many cases closing at 440-volt alternating current was used because of the greater distance between the signal station and the anchor bridge on which the circuit breakers were located.

The line circuit breaker relays and associated manual control were located on switchboard panels in the signal towers adjacent to these switching stations, of which there are about 30 in the electric zone, controlling 4 to 38 circuit breakers each. This fault clearing scheme had the advantage, found in pilot-wire relay

Paper 48-170, recommended by the AIEE switchgear committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Manuscript submitted February 18, 1948; made available for printing March 10, 1948.

schemes, of causing the two circuit breakers associated with any faulted circuit to trip simultaneously, a very desirable feature in the earlier days of inductive coordination with neighboring communication circuits.

On later extensions of the railroad electrification, a local definite time-delay relay was applied to the live tripping-power source at each switching station. This provided time, before automatic tripping, for the insertion of the power supply resistors, thus eliminating the necessity for the extension of the automatic control wire. With careful timing, practically simultaneous tripping of circuit breakers on through circuits resulted.

The great disadvantage of the resistance-insertion scheme was the relatively long time interval required to clear a fault, usually about 16 to 18 cycles (on a 25 cycle basis) or about 0.7 second for all the associated apparatus to function in sequence.

Need for Faster Fault Clearing

When the power supply, from the railroad-owned and operated station at Cos Cob, Conn., was augmented in 1915 by purchased power from the New York Edison Company at West Farms (East 174th Street, New York), this same resistance insertion scheme was used at that supply point. Later, in 1927, when three additional supply stations using frequency changers were installed, these also had the resistance-insertion scheme incorporated in their circuits.

It was soon found that the resistance insertion under fault conditions greatly impaired the system stability; and frequency changer stations would often drop out of step on faults. On severe faults, the Cos Cob station would sometimes drop out of step with the New York Edison supply, especially after 1936, when this supply was transferred from a segregated 25 cycle machine to the 25 cycle bus at the Hell Gate station of that system. By this time the railroad system loads and swings were increasing in magnitude, and fault conditions were becoming more severe. The protection scheme was becoming inadequate, and faster fault clearing was clearly indicated.

The matter of securing larger capacity single-pole circuit breakers for instantaneous tripping was investigated by the railroad with various manufacturers in 1935. It was found that new circuit breakers of conventional design and of the capacity required could not be located on the anchor bridges as originally designed, and that such circuit breakers could be used only by the complete redesign of switching stations, involving a very considerable expense. A great advance in the art of circuit breaker design had been made since the date of design (1913) of the bridge-type circuit breaker, and the matter of applying some of these improvements in design to the existing circuit breakers to improve their performance had already been discussed with the manufacturer of these circuit breakers.

Original Circuit Breaker Design

The bridge type circuit breaker was quite rugged in construction when viewed in the light of circuit breaker design at the time of its manufacture, and is shown in Figure 3. It consisted of a cast iron main base carrying the two terminal bushings and current transformers, a nonmechanically and nonelectrically trip-free a-c solenoid mechanism and operating lever system, and a flat bottom, sheet steel tank, elliptical in shape. A removable hood and swinging door of cast iron supported by the main base provided a cover for the solenoid mechanism and operating lever system. The tank was fastened to a malleable iron ring carrying four studs for bolting to the main base, and required 25 gallons of oil for normal oil level. The main base was mounted on two cast iron uprights with diagonal cross ties located at the rear of the circuit breaker. The double-break butt-type contacts consisted of a heavy malleable iron cross-bar carrying both main and arcing plunger-type contacts backed by compression springs. These butted against the single stationary contacts screwed on the terminal bushings. A maple wood lift rod was attached to the operating lever system by means of a short link. It had $5^1/_2$ inches of travel with $5^1/_8$ inches break distance. Many of the circuit breaker terminals were originally porcelain bushings, although some of the last circuit breakers furnished had condenser-type bushings, and later, all were changed to this type. The top cap of these bushings carried the hinge jaws of hook-stick operated disconnecting switches. The contact jaws of these switches were carried on post-type insulators supported by brackets attached to the circuit breaker main base.

Electrical creepage and striking distances both outside and inside were made quite liberal because the ground (and all grounded apparatus) was one side of the trolley-rail circuit. Also, the circuit breakers being mounted directly over the tracks, were subjected to the soot and steam from the occasional operation of steam locomotives; and the salt atmosphere and highly repetitive duty imposed on the circuit breakers all demanded these liberal allowances.

The normal manual switching operations and frequent automatic fault clearing service performed by these circuit breakers was unusually severe, compared to normal power line service, occasionally

amounting to several operations per day on some circuit breakers. Nevertheless, they gave satisfactory performance for more than 25 years.

First Application of Modern Interruptors

Those familiar with the history of circuit breaker development know the great strides made in controlled arc interruption during the period 1928 to 1933. The deion grid[2,3] interruptors were developed during this period, and successfully applied to a large variety of oil circuit breaker designs. These new interruptors could be applied to circuit breakers in service almost as readily as to new designs, with very great improvement in performance, and reduction in contact maintenance and oil deterioration.

In 1933, the New Haven Railroad indicated interest in the possibilities of applying these modern interruptors to some of their bridge-type circuit breakers, at points where the duty seemed most severe. Investigation showed that it would be possible to adapt a light duty deion grid interruptor with finger contacts to this design of oil circuit breaker, and two of these circuit breakers were so equipped and placed in test service at Stamford, Conn., on a radial circuit feeding the New Canaan branch.

A minimum number of new parts consisting of stationary and moving contacts complete with Micarta wood lift rod, lift-rod guide, and an accelerating spring were supplied. After two years of service, with improved performance and reduced maintenance, the railroad felt justified in equipping about 80 circuit breakers, all located at the power supply points where the interrupting duty was the most severe, with these new contacts. This program was completed in 1938.

Inadequacy of A-C Closing Solenoid

In December, 1938, one of the bridge-type circuit breakers then equipped with deion grid contacts and located at the Cos Cob power supply point was subjected to two successive operations in clearing a near-by fault. On the second operation, which was a routine, manual, "CO" (close-open) operation, the operator observed considerable demonstration on the part of the circuit breaker. The fault was cleared, but with expulsion of considerable amount of oil and gas. Inspection showed contact burning in excess of that expected from interruption of two 3,000 ampere faults. Further investigation indicated that this was due to closing-in against the high fault current rather than the interruption of the lower value with resistance inserted. This closing-in difficulty was attributed to the inherent characteristics of the a-c closing solenoid which lacked sufficient power to close and latch the contacts against the magnetic blowout forces of heavy fault currents.

In order to verify the foregoing analysis and to determine if d-c operation of the closing solenoid would adequately rectify the closing-in difficulty, a deion grid circuit breaker was returned to the manufacturer for laboratory tests. Arrangements were made to obtain closing-in tests with either 440-volt 25-cycle control voltage, or direct current supplied from a Rectox rectifier impressed on the closing solenoid. The circuit breaker was closed-in against low-voltage short-circuit currents over a range of 4,100 to 33,100 equivalent rms amperes. A total of 12 operations with the a-c closing power indicated that the circuit breaker could close successfully against 5,000 amperes, but would fail to close against 10,000 amperes. A total of 20 operations with the d-c closing power were all successful up to the maximum value of 46,200 amperes, crest value of the first current peak. Figure 4*A* is an oscillogram of a typical failure to close with a-c control, and Figure 4*B* is one for a successful closing with d-c control. In both cases the equivalent rms value of the fault current was approximately 20,000 amperes.

Need for Additional System Data

Although the circuit breakers, newly equipped with deion grids, were giving the expected improved performance with reduced arcing time, the over-all fault clearing time of approximately 3/4 second was not materially reduced. The major portion of this time was consumed by the resistance-insertion scheme already described. The only way of reducing this time would be to make the line circuit breakers trip instantaneously; thus re-

Figure 2. Diagram of 3-wire system showing sectionalizing arrangement and the former resistance. Insertion scheme for fault clearing (now abandoned)

quiring them to interrupt the total fault current. System stability and increasing loads were making this change more and more imperative. This raised the question of circuit breaker interrupting requirements under system fault conditions. Accurate data on system fault currents were not available, but rough calculations indicated that at the major sources of power the fault currents might approach 25,000 amperes.

The deion grid contacts already installed on some of these circuit breakers were more than adequate for interrupting the 3,000 amperes required under the existing fault clearing arrangement, but they had not been applied with the view of any major change in interrupting requirements. Laboratory tests and field experience with this interruptor in modern circuit breakers had proved its adequacy for the intended service, but the interrupting limit when installed in a single-pole slow-speed 24-year-old circuit breaker for 11-kv 25-cycle service, had never been demonstrated. It was obvious that it would not even approach the possible 25,000 ampere requirement, equivalent to a 700-mva 3-phase interrupting rating. New circuit breakers of modern design of this rating were of dimensions and weight that precluded any possibility of their use in the existing switching stations. The only alternative left the railroad was to further explore the possibilities of making these old circuit breakers as adequate as possible. It was then obvious that accurate data on fault currents, system stability, and general system characteristics were required before any satisfactory and economic solution of the problem could be obtained.

A-C Network Calculator Studies

In June, 1938, it was decided to study system fault conditions on the a-c network calculator. Some previous calculations had been made in 1913, in connection with inductive co-ordination studies, of fault conditions existing at that time. From these earlier studies, augmented by data and methods outlined by A. W. Copley[4] in 1920, fairly accurate data were obtained on trolley-rail, feeder-rail, trolley-feeder, and their mutual impedances. From the various manufacturers the necessary data were secured on line auto-transformers, station step-up transformers, and generator impedances. A complete network impedance diagram of the system was laid out, and set up on the a-c network calculator at East Pittsburgh for existing and possible future conditions of maximum generation.

Figure 5*A* shows a section of the impedance diagram for circuits in the vicinity of Cos Cob power supply. Figure 5*B* shows how this was set up on the network calculator. Figure 6*A* shows the value of a bus fault in rms, symmetrical amperes, and its components obtained by reading around the mesh circuits shown. Figure 6*B* shows how the values obtained on the network calculator are transformed to the actual 3-wire circuit values, and Figure 6*C* shows the application of these values to four trolleys and four feeders.

By taking bus faults at each sectionalizing station, and obtaining the currents in the mesh circuits adjacent thereto, sufficient basic information was obtained not only to determine the maximum instantaneous symmetrical fault currents at each station, but to calculate later the proper relay setting for clearing faults on all circuits.

Figure 7 sets forth in diagrammatic form the value of the fault current at various stations under maximum generating conditions. It will be seen from this diagram that the maximum interrupting duty on any line circuit breaker is at Cos Cob, where the value of the instantaneous symmetrical fault current is about 16,000 amperes for a trolley-rail fault, and about 14,000 amperes for a trolley-feeder fault. Therefore, if the bridge-type circuit breakers could be redesigned to interrupt these values, they would fulfill all requirements for instantaneous operation, and the resistance-insertion scheme could be abandoned. The a-c network calculator studies showed further that if faults could be cleared within the first quarter of a second (6 cycles) the stability of the system would be materially improved, and the chances of the various power supply stations falling out of step during faults would be greatly reduced.

Application of Heavier Duty Interruptors, and Other Changes

While it could be safely assumed, taking into account all associated factors of relay time, circuit breaker contact parting time, and the time constants of the system, that the circuit breakers would never be called upon to interrupt the asymmetrical values of the fault current on instantaneous tripping; nevertheless, the interruption of rms symmetrical values of 16,000 amperes was obviously beyond the capacity of the interruptors previously applied.

Previous tests on circuit breakers of

A—System impedance diagram

B—A-c network calculator impedance diagram for (A)

Figure 5. Impedance diagram for part of system and its application to network calculator

modern design had indicated that heavier duty interruptors and greater contact travel at higher speeds than used for the original modification of these circuit breakers would be required for such service. Even with these features, there was considerable doubt as to whether the cast-iron main base, and other cast-iron components would withstand the increased mechanical forces to be encountered in such service. Nevertheless, it was considered worthwhile to modernize, and to make laboratory tests on a sample circuit breaker to determine the necessary changes.

The following minimum quantity of new parts was deemed necessary to give an adequate circuit breaker.

1. New type *F*, 23-kv deion grid contacts.
2. New levers, lever supporting frame, and mechanism hood to increase travel to approximately eight inches.
3. New stronger and deeper tanks requiring approximately 30 gallons of oil.
4. New accelerating device and oil dashpot to obtain increased speed and prevent excessive rebound on opening.
5. New six-pole auxiliary switch, operating levers, and housing to isolate switch from the solenoid mechanism and lever compartment.
6. New electrically trip-free control relay and housing.

Laboratory Tests on Revised Bridge Type Circuit Breaker

In view of the operating duty required on the circuit breakers and the fact that the revamped circuit breakers would be of non-oil-tight construction, the test schedule was set-up on the basis of an 0-2 minute "CO" (close-open) circuit breaker duty cycle. These laboratory tests were to be made at 11-kv 25-cycle single phase, over a current range up to 16,000 amperes, rms, interrupting; and 40,000 amperes, crest, first peak, closing. Several series of closing and interrupting tests were made to determine the necessary modifications required to obtain a modernized circuit breaker which would give satisfactory performance in the proposed service.

The first series of tests were made on a modernized circuit breaker utilizing the new parts previously listed. Closing was from a 100 volt d-c source, and tripping was from a 114-volt 25-cycle source; both operations being controlled by the laboratory motor operated cam switches. On the seventeenth operation, a "CO" shot, the circuit breaker contacts froze when closing-in against a first 1/2-cycle peak of 38,400 amperes, crest. The sticking of the contacts was due to rough contacts resulting from the 16 previous operations without contact inspection or maintenance.

The next series of tests was similar to the first series, except closing power was obtained from a 440-volt 25-cycle Rectox

Figure 7. Curve showing values of trolley-rail and trolley-feeder fault currents at various parts of system

rectifier adjusted to give 110 volts direct current on the closing coil. The control of the circuit breaker was modified to utilize the new a-c electrically trip-free control relay and auxiliary switch which had been added. This second series of tests ended when both cast-iron supporting frames and a corner on the main base casting were broken. On this test the circuit breaker closed-in against a peak current of 51,000 amperes, crest, and interrupted 14,300 amperes, rms.

The broken main base, repaired by welding, was mounted on a new structural steel supporting frame for the next series of tests. This casting again cracked on a high current shot, making it evident that the increased elasticity of the new structural steel frame was not sufficient to absorb the shocks incident to the interruption of these high currents.

For the fourth series of tests the circuit breaker unit was suspended between compression springs, as shown in Figures 8 and 9, to further relieve the stress on the main base. This series of tests was quite satisfactory with respect to the circuit breaker structural details, but the oscillograms showed excessive rebound of the moving contact on the high current interruptions. Investigation revealed this rebound was caused by the differential pressure between the contact and mechanism ends of the lift rod.

The next three series of tests were made to determine the effectiveness of minor changes found desirable to eliminate the excessive rebound, reduce oil loss, and to prevent drainage of oil onto the bridges on which these circuit breakers were mounted. These changes included replacing the all wood Micarta lift rod with a combination steel and wood Micarta lift rod, reducing the baffling around the lift rod and lift-rod guide, replacing the circuit breaker compartment open vent with a baffled vent, and adding an oil conservator to trap the oil draining to the bottom of the mechanism compartment.

The eighth and final series of tests was made on the circuit breaker modernized with parts made from the drawings as changed for manufacture in quantity and as shown by Figures 8 and 9. During this time, field studies indicated that d-c control from a 115-volt storage battery would give the most desirable and economical control source. This series of tests was made with the changed control and the operations were made on a "CO"-2 minute —"CO" duty basis instead of an "O"-2 minute —"CO" duty cycle. These last series, consisting of 19 tests, gave further indication that a modernized circuit breaker had been produced, which would give very satisfactory service at a relatively small increase in size and weight.

A brief review of the foregoing development tests shows a total of 109 interrupting tests; about half being "O" shots, and the other half "CO" shots. Of the total interruptions 62 were at current magnitudes in excess of 10,000 amperes, rms, and 47 were at current magnitudes below 10,000 amperes. Of the latter, 19 interruptions were in a current range of 5,000 to 10,000 amperes, rms. The maximum current interrupted was 22,800 amperes, rms on a straight opening operation as shown by the oscillogram Figure 10*A*. The maximum making current was 54,400 amperes, crest, on a "CO" operation in which the current interrupted was 15,200 amperes, rms. The oscillogram shown in Figure 10*B* shows a typical "CO" operation in which the circuit breaker closed against 52,800 amperes, crest, and interrupted 16,400 amperes, rms. A careful analysis of the oscillograms on the higher current interruptions showed average impulse pressures of approximately 60 pounds per square inch, and only six shots with pressures in excess of 150 pounds per square inch. These higher pressures were not confined to the highest current interruptions, but all were incident to a high instantaneous current with an accompanying discontinuity of arc voltage. It is

Figure 8. Contacts and details of modernized test circuit breaker

A—Interrupting 22,800 amperes, rms

B—Closing against 52,800 amperes, crest and interrupting 16,400 amperes, rms

interesting to note that the operation having the maximum impulse pressure was perfectly satisfactory, both mechanically and electrically. Of the total of 109 operations, there were no electrical failures on interruption, and only one electrical failure on closing-in due to rough contacts, as previously noted in the first series of tests.

Rebuilding the Circuit Breakers by the Railroad

Having demonstrated by the foregoing comprehensive series of tests the requirements for the adequate modernization of the bridge-type circuit breakers, the manufacturer assembled a sample circuit breaker, and furnished, on the railroads' subsequent orders during the next six years, the required parts for the rebuilding of approximately 525 circuit breakers by the railroads' maintenance forces. This presented an extensive undertaking not only in removing the old circuit breakers from service, dismantling, reconditioning usable parts, which included machining the main-base castings, but in reassembling with new parts, testing, and replacing on the anchor bridges and reconnecting for service. All of this was accomplished without any interruption to railroad service.

This required very careful planning. At the Cos Cob power plant, part of an old boiler house was vacant and used only for storage. This was cleared and equipped with work benches for the assembly work, and arrangements were made whereby any machining of bases, and so forth, could be done in the power plant machine shop. Both alternating and direct current were available for testing, and adequate space was made available for parts storage, small stores and tools.

Before any switching station was taken out of service, conditions were reviewed with the local communication companies as to inductive co-ordination with the balancing transformer out of service at that station for an extended period of time. In all cases it was found possible to allow this which greatly simplified the field work, since all through trolley and feeder circuits could then be tied through with disconnecting switches, and the high tension connections could be removed one by one from each circuit breaker until the entire station was disconnected. The circuit breakers were then dismantled on the bridge, the parts to be reutilized carefully taken down and removed to Cos Cob, and all the old unused parts scrapped. In the cases where the anchor bridge switching stations were at the power supply points, only half the circuit breakers could be removed from service at a time, in order not to interrupt the power supply. The dismantling usually required about one week. This was followed by such maintenance work and rearrangement of supporting structures required after 25 years of service and to get improved clearances, and so forth, which required between two and three weeks more. In cases involving stub-end feeds, some temporary connections were required.

When this field work was completed, the gang was moved to Cos Cob for circuit breaker assembly. It took about six weeks to assemble 20 circuit breakers, the average number at a switching station. Figure 11 shows the assembly work.

The reassembly accomplished, the circuit breakers were tested, mounted on skids, with terminals crated, but without disconnecting switches or bracket insulators, loaded on flat cars and returned all together to their switching station. There they were lifted onto the bridge deck, skidded into place, further assembled with disconnecting switches, and reconnected to their high-tension and control circuits, all of which took another month or longer, depending on weather conditions. Before restoring the station to service, the circuit breakers were given a high potential test, the bushing current transformers were tested for correct connections and polarity, the bus differential protection (not described in this paper for lack of space) was checked, and each circuit breaker was timed with cycle-counter for tripping and closing time.

The first station was taken out of service in July 1940, and restored to service with new circuit breakers in the following October. The first five stations were revamped as to circuit breakers without undertaking any change in the control or relay scheme other than to substitute a 55-cell 80-ampere-hour storage battery for the former 110-volt a-c tripping and closing power, and to place any stub-end feed circuits on instantaneous trip. The resistance-insertion scheme was still used on all through circuits pending the completion of a new relay scheme then in the process of being developed.

Figure 12. Oscillogram of fault current and circuit breaker performance on prearranged fault

Redesigning the Fault Clearing Relay Scheme

The network calculator studies had indicated the magnitude of the component currents feeding a faulted bus from circuits in either direction, and from the local transformer.

Further calculations were made of the single circuit impedances between switching stations. These were added to the values for system impedance to the adjacent switching stations, found from the network calculator values of total fault current at that station. This gave the maximum impedance for such stub-end feed faults that might occur due to the possible sequential operation of circuit breakers on a through circuit. Similar approximate values of impedance were calculated for mid-way faults in the electrical center of through circuits, for insuring simultaneous tripping of both circuit breakers feeding such faults. Typical values of such faults are indicated in the diagram shown in Figure 7.

A careful survey of these calculations indicated that there were enough parallel circuits and the sections were sufficiently short so that with fairly accurate impedance data, instantaneous over-current relays could be used, and set high enough to operate only for faults in the section of trolley or feeder controlled by its associated circuit breakers. On some of the longer sections (of approximately seven miles) the relay settings are not very much above the maximum train load requirements, but the operation on instantaneous trip has shown an exceptionally high degree of selectivity. There have been very few operations of circuit breakers not directly in faulted circuits, unless there were unusual conditions of more than one paralleling circuit out of service.

Discussion with the communication interests during the early part of the development of the instantaneous overcurrent relay trip scheme revealed that sequential tripping of through circuits with this scheme, because of faster clearing, was less likely to cause inductive disturbances than the slower resistance-insertion scheme.

Beginning with the fifth station revamped (in 1942) each station was equipped with two relay trip busses, to which any or all relays could be connected. One bus was energized by a local definite time-delay relay for use with the resistance-insertion scheme, and the other was normally energized, for instantaneous trip.

The old type *B* relays were replaced by new type *SC* over-current relays. The settings were left the same as the old type *B*, and all were connected to the delayed tripping bus. By June, 1944, all the stations between Cos Cob and West Farms had been changed to new circuit breakers with new relays, and then, in rapid succession, the relays on adjacent bridges were reset to calculated settings and connected to the instantaneous trip bus until all were changed. Thereupon, the resistance-insertion scheme was cut out of service between Cos Cob and West Farms. In due time all resistance-insertion in circuits west of West Farms and east of Cos Cob was entirely abandoned.

The war had a serious retarding effect on the revamping program, necessitating but a skeleton maintenance force to do all the work, although the material was allowed to come through, as essential, on the required priorities. There was not a single serious accident chargeable to this work, even though much of the field work was performed over or near energized 11-kv trolley and feeder circuits.

Operating Results With Rebuilt Circuit Breakers

The first sample circuit breaker went into service in the latter part of 1940, in the yard at Port Chester, a zone where the symmetrical fault currents were on the order of 13,000 amperes, rms. In the following three years this circuit breaker interrupted 58 short-circuits and had approximately 1,200 mechanical operations, most of the latter being for test and isolating purposes. In this period, the arcing horns were renewed five times, and the stationary and moving contacts were renewed once. Other maintenance included dressing of contacts, checking adjustments, and renewing oil. On two occasions the deion grid stack lower plates on the line side were found cracked, and were replaced. Of two other circuit breakers in similar service at different locations, one circuit breaker had one stack with the lower plates cracked, while the other circuit breaker did not. The cracked plates were due to the excessive pressures which occasionally occur as pointed out under the comments on the laboratory tests. While the occasional cracked plates did not result in any failure to interrupt, a re-enforcing plate was inserted in the bottom of the deion grid stacks furnished during the latter part of the program. These re-enforced stacks were immediately placed on the two yard circuit breakers and they have given no further trouble. However, due to infrequent trouble and satisfactory operation in the last four years, it has been unnecessary to add the re-enforcing plate to the deion grid stacks already installed. In order to increase the life of the parts subject to arcs and arc gases, the area of the

contacts protected by arc-resistant alloys was increased, and renewable inserts were added to the tank liners.

Two circuit breaker failures have occurred since the start of the program. One failure was experienced during the hurricane in September, 1944, due to excessive moisture getting into the circuit breaker after three successful interruptions within a couple of hours. A second circuit breaker failure occurred in 1947, when on an automatic trip-out, the circuit breaker hung-up in a partially open position and thus failed to clear the circuit; requiring clearing from the back-up protection.

The entire system with over 525 circuit breakers was rehabilitated by March, 1947, and operating on the new instantaneous relay scheme, with excellent performance. Figure 12 shows an oscillogram of fault current and circuit breaker performance for a prearranged fault midway between two adjacent switching stations at Devon and Woodmont, Conn. Some sequential operation of circuit breakers is noted, but the entire fault clearing time is but four cycles. Five separate faults were made on this occasion, all of which showed practically identical circuit breaker performance.

The outstanding features of this modernization program is that by a series of laboratory and field tests, a 25 year old circuit breaker and protection system was completely modernized to satisfactorily handle six times the interrupting duty and reduce the fault clearing time from 0.7 to 0.2 second. This improved performance has been accomplished with very little increase in weight and space. Due to the mechanical structure of the old circuit breakers, preliminary studies did not show much probability of obtaining the desired results. The present satisfactory system performance appears to have justified the co-operative and persistent efforts required to complete this project.

The cost of rebuilding these circuit breakers was about half the cost of new single pole circuit breakers of modern conventional design adequate for the service; and the switching station changes were but incidental as compared with what would have been required with new circuit breakers. The new relay scheme added approximately 10 per cent to the total cost.

As the result of this rebuilding program, the railroad now has line circuit breakers with six times their former interrupting capacity, with faster fault clearing, reduced maintenance cost, and improved system stability and reliability.

Discussion

W. M. Leeds (Westinghouse Electric Corporation, East Pittsburgh, Pa.): No mention has been made of the effect of system frequency on the problem of raising the interrupting capacity of these bridge-type circuit breakers. It has been observed by those familiar with circuit breaker testing that modern oil circuit breakers, capable of interrupting fault currents with relatively short contact separation, show increased variability in performance as the circuit frequency is lowered. The reason is tied up with the fact that a-c oil circuit breakers interrupt at a normal current zero, and the maximum "waiting time" for a current zero after reaching the minimum contact gap for interruption is proportional to the period of the current wave. Let us assume that the minimum arcing time for a given circuit breaker is 0.03 second, corresponding to a contact gap of two inches. The most unfavorable condition is represented by an arc reignition just ahead of this point in the stroke, extending the arcing time by one-half cycle to the next current zero. At 60-cycle frequency this would add 0.0083 second or 28 per cent to the minimum time, whereas at 25-cycle frequency the increment would be 0.02 second or 67 per cent more arcing. On the basis that the arc energy varies as the square of the arcing time (which assumes a linear increase of arc voltage with time) a little calculation shows that the maximum arc energy at 60-cycle frequency would be 63 per cent greater than the minimum, but at 25-cycle frequency 178 per cent greater. The ratio of the maximum energies is 1.7 to 1, suggesting the need of a circuit breaker having 70 per cent greater rupturing capacity when used at 25-cycle frequency rather than at 60 cycles. While these figures are only approximate, they show why a duty of 16,000 amperes at 11 kv single phase (equivalent to 460,000 kva* at 19 kv three phase) required reinforced construction in standard 23 kv 500,000 kva interrupters so that satisfactory performance at 25-cycle frequency might be assured under the most adverse conditions. The successful outcome of this revamping program was due to the persevering efforts of many individuals and demonstrated once more the indispensability of a high power testing laboratory.

H. D. Braley (Consolidated Edison Company of New York, Inc., New York, N. Y.): The Consolidated Edison Company of New York was directly connected with the improvement program, initiated by the New Haven Railroad, and gave its full co-operation in such work as was required to put into effect successive steps of the improvements.

In the past, insertion of grid resistors in the railroad feeders at West Farms substation was frequently causing unavoidable "pumping" (successive opening and closing) of oil circuit breakers, which normally short-circuited the resistors.

Repeated cycles of pumping on fault conditions were causing frequent operation of resistance circuit breakers, which resulted in fast deterioration of circuit breaker oil and burning of circuit breaker contacts, made of the best grade of material available. This required a rigid schedule of circuit breaker maintenance, covering their inspection and overhaul every six months.

Due to the elaborate scheme of insertion of resistors, and of energizing the a-c tripping source to the railroad bridges, the fault clearing time was relatively high. This, combined with pumping of resistance circuit breakers, was affecting the stability of the interconnection and resulted in frequent separations between the New Haven and the Edison systems.

When the old method was abandoned, maintenance at the West Farms substation was considerably reduced. Grid resistors, resistance circuit breakers and associated equipment were finally retired. The number of separations between the two systems appreciably decreased.

Faster clearing time at the railroad bridges permitted a 40 per cent decrease in the operating time of back up relays at West Farms and reduced the duration of voltage disturbances on the Edison system.

In conclusion, the modernization program of the New Haven Railroad resulted in an excellent solution of a difficult relaying problem. Recognition is made of the fine co-operation which we had from the New Haven Railroad in solving our problems connected with the modernization.

H. F. Brown, H. A. Travers, and **C. A. Woods, Jr.**: Braley's comments indicate that the modernization program described was far reaching; not only improving operation on the railroad system, but also the interconnected systems supplying power to the railroad.

Leeds' discussion emphasizes the possibility of increased severity in interrupting duty imposed on the circuit breakers due to the lower system frequency. While this was not brought out in the paper, there was evidence of this possible increase in energy, both in the laboratory tests and in field service. The 25-cycle system frequency, undoubtedly, made the task of satisfactory circuit breaker modernization more difficult.

An Instrument for Recording Continuously the Salinity, Temperature, and Depth of Sea Water

A. W. JACOBSON
MEMBER AIEE

MANY physical phenomena in oceanography can be determined from knowledge of the horizontal and vertical distributions of the salinity and temperature of sea water. Current practice in obtaining salinity measurements makes use of sampling devices and chemical analyses.[1,2] Surface temperatures are measured with conventional-type thermometers and thermographs. Measurements at subsurface levels are made with reversing thermometers[1] and with mechanical "bathythermographs,"[3] which provide a record of temperature as a function of depth. Although these methods provide highly accurate information, the lack of continuity of salinity data may at times limit their usefulness. Also, considerable time is consumed in the procedures of sampling, analysis, and plotting of data, and it is often difficult to retain navigation.

The instrument described measures continuously the temperature and specific electrical conductance of sea water, and computes from these its salinity. The measured temperature, the computed salinity, and the depth at which the measurements are being made are recorded simultaneously on a strip chart.

The instrument operates from a 115-volt 60-cycle supply and is unaffected by normal voltage and frequency variations or by the vibration and motion of the vessel. It measures the temperature of the water over a range from 28 to 90 degrees Fahrenheit with an error not greater than 0.2 degree Fahrenheit. Salinity is determined over a range from 20 to 40 parts per thousand (‰) with an error not greater than 0.3‰. The maximum error in depth over the range from 0 to 1,200 feet is 12 feet. The time lag of the instrument is governed primarily by the thermal speed of response of the resistance thermometer bulb, which has a time constant of 0.45 second.

Although the precision is less than that obtainable by standard reversing thermometers and titrations for chlorinity, this disadvantage is offset for many purposes by the convenience of continuous measurement, and the prompt availability of the temperature and salinity data.

Several earlier instruments for determining the salinity of sea water from conductivity measurements are described in the literature.[4-8] These instruments employed Wheatstone bridge circuits by which the conductivity of a batch or flowing sample of sea water was compared with that of a standard of known salinity contained in a sealed cell while both were maintained at the same temperature. While this method provided a high degree of accuracy, the use of a sealed cell for temperature compensation introduced a serious time lag, and limited the practical application of these equipments.

Paper 48-173, recommended by the AIEE instruments and measurements committee and approved by the AIEE technical program committee for presentation at the AIEE North Eastern District meeting, New Haven, Conn., April 28-30, 1948. Manuscript submitted February 9, 1948; made available for printing March 3, 1948.

A. W. JACOBSON is with The Bristol Company, Waterbury, Conn.

Contribution Number 428 from the Woods Hole Oceanographic Institution.

Material for this paper is based on studies and results of a joint research and development project by the Woods Hole Oceanographic Institution and The Bristol Company under the sponsorship of the Navy Department's Bureau of Ships.

The author wishes to acknowledge the contributions of Dr. Alfred C. Redfield, Allyn C. Vine, and Dr. William L. Ford and John F. Holmes, all of the Woods Hole Oceanographic Institution, who, respectively, directed the project, initiated the development, and conducted the field tests; and John L. Russell of The Bristol Company, who was responsible for the mechanical design.

General Description

The instrument consists of three major units; the measuring elements assembly, the computing and recording mechanisms, and the amplifier unit. The electrical connections between the units are made with multiple-conductor cables and plug-type connectors, so that no tools are necessary in hooking up the equipments. Figure 1 shows the instrument installed in the Woods Hole Oceanographic Institution research vessel Balanus.
